Meyer of Göttingen, in 1892, described several cases in which a kidney showing chronic tuberculosis, by serial sections, he demonstrated local tubercular foci in the urinary tubules that had not extended from above or below, and which could not have come by penetration of the wall of the tubule, as its membrana propria remained intact. He explained this by the assumption that the bacilli have been secreted from the blood by the vessels of the glomeruli, found their way along the tubule in the urinary stream and lodging on its wall set up their specific inflammation. He calls this form of infection "Secretion Tuberculosis." He quotes, in support of his theory, Reisser and Orth, who have demonstrated the same process in pyemic abscess of the kidney, and have shown that bacteria and even foreign bodies, as drops of fat, can be secreted through the glomeruli. Borrell, in this experimental production of renal tuberculosis by the injection of the bacilli into the aorta, has demonstrated their presence in the walls of the vessels of the glomeruli, unaccompanied by inflammatory change. Thus there is a second way in which the bacillus in the blood may produce renal tuberculosis.

Time is not given for the consideration of urogenital tuberculosis though the review of the subject does not seem complete without some mention of this form, and the discussion which its pathogenesis has occasioned.

In this variety the kidney, ureters, prostate and testicle in the male, and the tubes and ovaries in the female, are oftenest affected, much more rarely the bladder. This form of the disease is, as is natural, much more common in the male, and indeed is very rare in females.

Rayer, as early as 1837, showed that a healthy bladder may be an intermediate between a tubercular testis or prostate, and a similar condition of the kidney. The experiments of Alberran, in which by ligation of one ureter and injection of tubercle bacilli into it above the point of ligation, he proved that the disease may ascend along this tract, is conclusive, but is significant as being the only instance, in many experiments by different observers, which was successful. The ascending form is favored by Rokitansky, Lancereaux, Klebs, Steinthal, Guyon, Duret, and Virchow. Later writers, while acknowledging the possibility of an ascending form, incline to the greater frequency of the descending. So Ziegler, Birsch-Hirschfeld, Senator, Carmargo, Dickinson, Roberts, Casper, Hamill and Israel are more or less positive in the opinion that while tuberculosis may ascend the ureter, it is oftenest primary in the kidney.

The case reported belongs to the chronic variety of renal tuberculosis. The sequence of events is doubtful, and the case might reasonably be regarded as one of the rare instances of renal tuberculosis secondary to cryptogenic infection through the mucous membrane of the intestinal or respiratory tract. However, the adhesions at both apices, and the cavity on the right side, together with the fact that the lesions of the lung is of the type of an infection by inhalation, suggests that, probably the disease was primary in the lung, and that the older lesion was masked by a sudden extension of the process about it, at a comparatively late period, and shortly before death.

The histologic portion of the above report is from the Pepper Laboratory of Clinical Medicine.

IS MALARIA A WATER-BORNE DISEASE?

Presented to the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY JOHN M. BATTEN, M.D.
PITTSBURG, PA.

Malaria may, to some extent, be a water-borne disease, but that the malaria plasmodium or poison gains admittance into the system wholly by way of the stomach, we think we have ample evidence to lead us to doubt. The plasmodium malariæ or malarial poison certainly gains admittance into the system through the respiratory organs as well.

I will give a hasty review of the disease as it came under my observation in 1864 and 1865. The *Valley City*, to which I was attached, had a roving permission to cruise in the sounds of North Carolina and up the rivers that empty into these sounds. The water of the sounds at times is brackish, as it has connection with the ocean through Ocracoke Inlet. The intensity of the disease and the number of cases that occurred increased in the following localities in the order named: 1, the region of the Pamlico River, upon which Washington, N. C., is situated, is rather free from malaria, though cases occur there; 2, the region of Chowan River, Blackwater River, Meherrin River, and 3, the regions of Roanoke River and Neuse River. Again, on Roanoke Island there is no vegetation, except in the northern part of it, where there are a few scrub oaks. The island is sandy and barren. Yet, one day on that island, with Dr. Walton of the 103d Pennsylvania Regiment I saw a hundred cases of malaria, but many of these cases may have been transferred from other localities. The water used there for drinking and cooking purposes was boiled water taken from the wells on the island.

The water for drinking and cooking purposes on the *Valley City* was either boiled or distilled, taken from the boiler, cooled and kept in a covered vessel for that purpose. Now, when the *Valley City* was for a long time up the Roanoke River or other rivers, the cases increased in number and intensity, according to the locality in which she cruised. When cruising up the Roanoke River for a long time the treatment of the disease in many instances would be of no avail, but afterward, when cruising in the sounds or the Atlantic Ocean the disease would respond to treatment, so that there would not be a single case of malaria on board. Afterward, cruising up any of the aforesaid rivers the number of cases and the intensity would increase according to the locality. In the region of the Roanoke River it was intensely malarious; as forest swamps and fogs prevailed there, and many places in this region were impenetrable to man or even the wild beasts of that locality. Why was there a difference in the type of the disease and also the number attacked while in these different localities? It was not the water we drank nor the food we ate, for the water we drank and used for cooking purposes was boiled or distilled. The boiler received its water by pumping from the river, sounds or ocean. Therefore the malarial poison must have been taken into the system through the respiratory organs.

In the fall of 1865, at Cairo, Ill., following a very hot and dry summer, the months of September and October were exceptionally dry and hot. I reported for duty on the United States monitor *Oneota*, lying off Cairo on the Ohio River, Oct. 6, 1865. Malarial fever was prevalent everywhere in that vicinity. A large barge moored to the *Oneota* was filled with cases of malarial fever of a pernicious type. We used water for drinking and cooking purposes that was boiled or distilled as on the *Valley City*. What I want to show particularly is, not only that malarial fever prevailed notwithstanding that the water for drinking and cooking purposes was boiled, but that it is not necessary to have a wet season follow a dry and warm summer to produce malarial fever or the plasmodium malariæ. Up to Oct. 6, 1865, there had been no rain. The Ohio and Mississippi Rivers were very low, and along the banks of the Ohio in the vicinity of Cairo there was a green scum on the surface of the river, extending some distance from the shore. Yet, as I have said, there was malarial fever prevailing everywhere in that locality.

Again, in the Western States and in Pennsylvania malarial fever has been actually plowed out of existence. The agriculturist who, for the first time, turned up the soil, suffered the most from malaria, but as the soil was more and more stirred up the less severe and the less frequent would be the attacks, so that today in many localities where the disease was most prevalent, there are no cases of malaria. Was it the water that these early settlers drank, the food they ate, or was it the air they breathed by which the plasmodium malariæ or malarial parasites were conveyed into their system?

I hope I have made myself plain on this subject. It is only by observation and experience that we can arrive at a true understanding in regard to this matter. The more plasmodium malariæ that is taken into the system, the oftener the paroxysms of fever will recur, as every day, every second day, etc. Pernicious fever occurs in localities in which the plasmodium malariæ or malarial poison is most intense and most concentrated.

CONVERGENT STRABISMUS.

A CLINICAL LECTURE DELIVERED IN RUSH MEDICAL COLLEGE.

BY ALFRED HINDE, M.D.
CHICAGO, ILL

I. ITS ETIOLOGY.

We have read that a child's education ought to be started before its birth; and, in our opinion, the consideration of strabismus is incomplete unless we remember that the ancestral history of these cases often contains an account of one or more persons where the visual line of one eye deviated from the object looked at with the other eye. Such predisposition undoubtedly tends to the production of squint in the offspring. The young of all animals remain with closed eyes for a variable period after birth. The human offspring is no exception. Whether this is due to a sudden change from darkness to light, or because the retinal functional development is inadequate for useful purposes, or because the brain itself is dormant, or because of all these several conditions combined, is unknown. The baby automaton has not yet awoke to the necessities of vision. Its functions are of the lowest forms of life. Its brain, as such, is yet a blank. The first promises of intellectuality are evident when it opens its eyes about the eleventh day (Petersen) and peers around. For some time afterward its vision is general and not special. Its rolls its eyes around regardless of any single object and its attention can not be arrested for a moment by ordinary objects. The center in the brain is then awakening and its anterior prolongation, the optic nerve and retina, is becoming aroused to active life, but as yet the perceptive visual centers of the brain are not alive to the requirements of binocular vision. The eyes roll according to the uncontrolled nerve explosions sent to the external ocular muscles. The complicated government of visual center over motor center is not yet completed, and will not be until the higher center can receive and appreciate the image of an outside object formed on the retina of the observing eye, in short, until the occipital cortex has grown into a *sentient* perceptive center and asserted its control over the motor centers of the muscles of the eye. The greater the illumination of an object the more quickly it arrests the infant's attention; hence a bright light possesses a first charm to the steady gaze. The retina and entire visual tissue need a strong impulse to whip them into useful activity. By continued practice the function of vision is developed and at last the perceptive visual centers can value at its true worth binocular single vision, and they control the motor centers of the nerves that pass to the eye muscles and so regulate their nerve explosions that the visual line of each eye accurately meets at the object looked at. Briefly, the cerebral function of binocular vision is established "by the end of the second month (Petersen) and we will assume at the same time that the acuity of vision of each eye is alike and perfect. In such a subject there is no likelihood of strabismus and it can only occur from acquired pathologic changes in the ocular tissues. Animals' eyes have a hypermetropic refraction and the newly born human eye is no exception. It is undersized until puberty[1] is reached and even then the majority of human eyes are slightly far-sighted.

The infant's eye being unduly short in its antero-posterior axis the vision of such an eye, in a condition of rest, is imperfect according to the extent of this shortening. In order to focus parallel rays from distant objects accurately upon its retina it must needs exercise its accommodation, because its dioptric system, unaided, has an insufficient refractive power for such rays. Such an eye is adapted only for convergent rays and these are not found in nature. Therefore this hypermetropic eye must either be contented with insufficient focal power, associated with a blurry retinal image and imperfect vision of an outside object, or it elects to use its ciliary muscle to relax its zonula and lens, so that the added refractive power thereby gained is adequate for punctate union of luminous rays entering its pupil. Within a limited range this function of accommodation can be exercised alone or without any associated convergence, and it is by such means that youthful far-sighted eyes can add to their established binocular vision the power of seeing distant objects clearly. With binocular fixation, therefore, and normal acuity of vision such eyes are free from the probability of strabismus. The infant considers only distant objects and in predisposed cases strabismus does not occur until the child's curiosity has called forth the desire to observe near objects. This intellectual accomplishment is not reached earlier than the second year of life and it is during this period[2] that our squint cases begin to develop. They increase numerically up to the sixth year and are of the convergent variety.

---

[1] Twelve to eighteen years of age. Landolt, "Accommodation and Refraction of the Eye," p. 411.

[2] According to Petersen (Amer. Journal of Insanity, July, 1896), a normal child begins to distinguish colors correctly about the age of two years.

We see that it is not the distant object that brings out the strabismus, but the nearer object. We have averred that parallelism of the visual lines was consonant with distant vision. The two visual lines were accurately fixed upon the far away object, we had no strabismus.

The near object has called forth a new function, viz., that of convergence of the eyeballs. The function of accommodation and convergence, save within narrow limits, act together. The eyes we have mentioned as seeing accurately at a distance without either of them deviating were somewhat hypermetropic, but the license existing between accommodation and convergence was enough to permit of sufficient exercise of the former for distinct vision, without calling forth the latter faculty. This amount of hypermetropia has been called *facultative* (Donders), and in amount, in our example, is insufficient for the development of squint.

A higher degree of far-sight can not thus be neutralized. The link of union between accommodation and convergence is now put upon the stretch and accurate vision, *i.e.*, punctate focusing of rays upon the retina, can only be done by a greater refractive power of the observing eyes, while this can alone be accomplished by still greater contractions of the muscles of accommodation, and this stronger nervous impulse can not be exercised singly.

In the posterior part of the floor of the third ventricle of the brain and in the floor of the aqueduct between the third and fourth ventricles are several groups of nerve cells that give rise to separate groups of nerve fibers. The nerve fibers are gathered together into the third nerve trunk, but these separate groups of nerve cells give off nerve fibers that have separate and distinct distribution to the motor apparatus of the eyeball. Three of these central nuclei lie side by side and undoubtedly have intercommunicating fibers for the functions of the distal structures of distribution, save within narrow limitations, are always exercised together. I refer to the nuclei giving origin to fibers going to the ciliary muscle, the most anterior central group of cells; to the sphincter of the iris, the group equally forward and to the outer side of the ciliary muscle group; and to the internal rectus muscle, the group of cells in the median line immediately behind the ciliary muscle group. Neither does the proximity of origin of the these fibers terminate the close relationship of function, because they travel side by side in the third nerve trunk and only separate where its lower division within the orbit gives off the short motor root of the lenticular ganglion. From this point the motor fibers to each internus travel alone and the fibers to the intra-ocular muscles after filtering through the ophthalmic ganglion travel together in the short ciliary nerves to within the eyeball and are supplied from the same plexus within the ciliary body, though they are not completely inseparable, as shown by numerous cases of separate paralysis of either the sphincter of the pupil or of the accommodative muscle alone.

Thus we see the close anatomic relationship of the functions of accommodation and convergence and find at the same time the reason for their almost[3] simultaneous activity.

It is undoubtedly a fact that each of these nerve groups can transmit an independent amount of nerve force, but this is of limited degree and the function of the three centers is practically an associated one.

Now we will suppose that our child, who is beginning to observe near objects, possesses a medium amount of hypermetropia (2 to 6 D.) and has established the faculty of binocular vision for distant objects. He may apparently see objects in the distance distinctly, for he does not deviate either eye from its proper line of direction. When he looks at the near object, however, the inaccuracy of his vision is of such a high degree for these divergent rays that he must needs contract to a still greater extent his accommodative muscles, and in doing so he oversteps the bounds of independent action of the ciliary groups of cells over those of the interni, and this excessive effort at focusing becomes associated with an excessive effort of convergence, with the resulting deviation of one eye; a sacrifice of binocular vision, but gaining a more accurate focusing of the object with the other eye alone. In short, a strabismus convergens is instituted, and seeing that it occurs only when looking at a near object it is called a *periodic strabismus*. At first this squint may not be constant for near objects, if the latter are large enough and well illumined. Its frequency of occurrence, however, usually increases until for near it becomes permanent and soon it occasionally appears for distance, while later it becomes a fixed condition for objects at all distances.

It may be observed that the squint changes from one eye to the other, either eye fixing the object. This variety is known as *strabismus alternans* and the vision of each eye is usually equally good. In the majority of cases however the eye that first deviates inward is the eye that continues to squint and sees less well. This is known as *strabismus concomitans*, because the squinting eye follows its fellow and the angle of deviation is always the same. In this latter variety of squint the vision of the two eyes may at first be equal, and in this as well as in other forms of strabismus when vision is present in the two eyes, a diplopia occurs, because the two lines drawn from the maculæ through the nodal points of the two eyes do not meet on one and the same object. The eye whose visual line is properly directed has upon its most sensitive retinal area, the macula, an image of the object looked at, more distinctly perceived than the image of the same object that falls to the inner side of the macular region of the deviating eye, upon a portion of the retina with fewer cones and hence less sensitive in perceptive elements. Thus you see that the images cast upon the two retinæ do not fall on corresponding areas, hence double vision exists and the nearer these images are together, with retinæ equally percipient, the less the difference in distinctness and the greater the annoyance this diplopia causes the patient. But strabismic children, if they realize its presence, do not complain of or mention this double vision.

If there exists in our little patient a still higher degree of hypermetropia (above 6 D.), together with binocular vision, the vision for distance may be so poor and the knowledge of the value of more perfect vision so little appreciated, and the efforts of accommodation so unavailing or unused, that the child appears to rest contentedly with the vision that exists, together with a condition of relaxation of its efforts of accommodation and convergence. In short, it retains its binocular fixation and is satisfied with its poor vision until the prolonged efforts of an insufficient accommodative power result in subjective symptoms of eye distress and headache, associated with positive inability to see small near objects in school work. The oculist is then appealed to, not because of the deformity of strabismus, for this is absent, but because of the eye distress and the insufficiency of useful vision. Convex lenses are prescribed that are an accurate measure of the deficiency and when worn the symptoms cease and the required studious work goes on satisfactorily, though usually with subnormal vision, because these eyes are not only illy formed, but also histologically imperfect.

---

[3] In point of time the contraction of the pupil occurs later. (Donders.)

In the foregoing illustrations we have seen that in the hypermetrope of low degree the accommodation was sufficient for perfect vision, without calling upon the aid of convergence, and binocular vision was maintained, with no strabismus resulting.

In our hypermetrope of medium amount the accommodative effort was so extreme for accurate near vision that it could not be exercised without calling forth an effort of convergence in excess of the requirements of binocular vision. Briefly, a deviation inward of the visual line of one eye had occurred, a strabismus was instituted and binocular vision was sacrificed upon the altar of more accurate focusing.

In the highest degrees of hypermetropia we have shown that binocular fixation is retained and accurate vision correspondingly suffers, although squint does not always occur. The preceding illustrations are the rule, but not the invariable rule.

In all, hypermetropia was present, and this error of refraction occurs in three-fourths of all the cases of convergent strabismus. The cause of the remaining one-fourth of the cases of converging squint remains to be explained. An eye with a normal refractive power, an eye that in a condition of rest of its accommodation, has the power of punctate focusing of parallel rays upon its retina; an eye whose dioptric system unaided has sufficient refractive power for perfect distant vision, an emmetropic eye, may be the subject of strabismus. Binocular vision may have been inaugurated but inevitably lost because of a loss of balance of the lateral eye muscles (Schweigger), a congenital weakness of the externi or a superabundant power of the interni, either congenital or acquired. This condition explains the cause of a majority of the remaining cases of inward squint, and the above muscular conditions combined have a very important bearing in the causation of the ordinary cases of hypermetropic squint, as we shall see when we consider the operative measures necessary for their cure.[4]

Again, a muscular weakness in the interni, usually congenital, but occasionally acquired from the exhaustion of overwork, even with a hypermetropic refraction, may permit of a divergent squint. The opposite is occasionally true with a myopic refraction, a refractive power that is relatively too great, an antero-posterior axis of the eyeball that is excessive, so that parallel rays entering the eye are brought to a focus in front of the retina, we may have a convergent strabismus, and this is due either to a superabundant power of the interni muscles or a deficient power of the externi. The adductive power of convergent strabismic eyes is commonly too great, may be congenitally so, may be acquired from constant effort at convergence with accommodation. The shortened distance between the origin and insertion of the internus as a constant quantity results in a permanent shortening of this muscle (Hansen-Grut's theory) and also of the superior and inferior recti.

Lastly, the more anterior insertion of the internus tendon—six millimeters from the cornea—gives it a a great advantage over the weaker externus, whose tendon is usually eight and occasionally ten, or even twelve millimeters from the outer limbus corneæ. Moreover, the position of rest of the entire ocular muscles is one of slight convergence of the visual lines.

Other causes of convergent squint are found in a congenital amblyopia of the squinting eye (Schweigger 30 per cent.) whose vision is too poor to exercise any efforts toward the establishment of binocular vision. It permits itself to be rolled inward by the stronger internal rectus, and so remains. Even in eyes where one has a greater error of refraction than the other, so-called, *aniso-metropia*—the one with the greater error, hence the poorer vision, has the least hold over the binocular fixation, and occasionally gives it up altogether and permits the internus to sway the eyeball inward. It is the rule in concomitant strabismus convergens for the eye with the greater error to be the deviating eye. Again in spasmodic conditions of the interni, produced by central, distal, or general causes, a convergent squint occurs, stays for a variable period, may recur, and happens generally after strabotomy, or in the constitutional conditions of children. This form is known as an *intermittent strabismus* and is infrequent.

Lastly, young patients are prone to squint where an acquired permanent opacity occurs as the result of some preceding inflammation of the cornea. Binocular vision, if instituted, is surrendered because of the inaccurate vision of the affected eye and the strongest muscle turns the eye inward or outward according to the relative strength of the individual muscles.

There are exceptions to the rule in strabismus, as elsewhere, and a few examples of this condition do not conform to the foregoing causative explanations. We occasionally see a case of squint, where only a lower degree of hypermetropia is present; where distant vision is accurate; and where the only deficiency we can find in the case is one of markedly diminished amplitude of accommodation for the age of the patient, an excessive convergence is instituted to increase an insufficient accommodation.

One of these cases I have lately had under my care where a patient, age 16, had an alternating convergent strabismus of 60 degrees with 20-20 vision in either eye without glasses, and who developed under atropin-paralysis only a total hypermetropia of 1 D. with the right eye, and 1.50 D. with the left, and who, after the atropin effect had entirely passed off, read with these glasses, either eye alone, 0.60 type of Snellen at a near point of eight and three-fourths inches (22 centimeters), showing an amplitude of accommodation of only 4.5 D. whereas it ought to have been about 11.5 D. at that age. We had a deficiency of 7 D., in short, the accommodation of a person of 40 years old. An advancement of each externus, with the requisite glasses for distance and near, resulted in a complete removal of the deformity. Another instance, where, with a high degree of hypermetropia, we have deviation inward, an example of this kind I have recently shown you in a hypermetrope aged 7 years with a Ht each eye of 7 D. Again, where, with a difference in the amount of the error of refraction in the two eyes, the one which has the lesser degree is the strabismic eye. The child recently before the class furnishes another, or central etiologic cause. She fell several feet one and a half years ago, and injured the occiput. This was followed by intra-cranial symptoms and intense headache, and soon afterward a concomitant strabismus inward and upward of the right eyeball, developed and has remained. The lateral deviation measured five millimeters and the ophthalmoscope showed a secondary optic atrophy most advanced in the right eye. As an observation, the retinoscopic test gave a total hypermetropia (under atropin) of the right eye, of 2.50 D., whereas in that of the left, straight eye, the amount was 3.50 D. Whether this error of refraction had any bearing on the production of the squint is a question. The more probable cause is the poorer vision of the right eye permitting the suspension of binocular fixation, together with the excessive action of the right externus muscle. The child is in her eighth year and was taken from school because of her failing eyesight.

---

[4] The last case of convergent squint I showed you was due to a combination of hypermetropic astigmatism, amblyopia and a lack of balance of the lateral muscles of the squinting eye. The patient, a girl of 18 years, had had a tenotomy of the left internus when 12 years of age, but objected to the use of glasses afterward. She appeared with a still present but very variable convergent squint. A parallelism for the distance but at 5 inches now, a deviation inwards of 15 degrees, and again 30 degrees, and still again an associated movement of the squinting eye outward, a divergence in fact being present. Yet in extreme abduction the left or squinting eye failed to roll out nearly as far as the other eye, even though a tenotomy of the opposing internus had been done six years ago. Here was present a marked weakness of the left externus muscle. The vision of the straight right eye was 20-40—; that of the left 20-200, while under atropin-paralysis that of the right eye was 20-200 and of the left eye 8-200. With each eye -3.50 D S $\frown$ -1 D cyl., axis 90 degrees, the right eye had 20-30 and the left 20-200. Therefore the best vision we could get with the straight eye was only two-thirds normal, and with the deviating left eye only one-tenth normal, yet the refractive condition of the two eyes was the same. The squinting eye was very amblyopic and besides had an anomalous muscular condition causing an ever variable direction of the eye, and the principal annoyance of which the patient complained was a constant diplopia. Further operative procedures were inadvisable and the above glasses were given to be worn constantly.

One other case, is of retinal pathologic causation, and, in point of time, the lesion that was the immediate cause of the strabismus convergens was congenital, yet the squint did not show itself until the second year of life, when the continued functions of accommodation and convergence were established for near objects. The cause of the squint in the left eye is due to a macular destruction of the retina from a subjacent choroidal atrophy. The latter of small area, sharply defined, single and due to a prenatal circumscribed choroiditis. This boy, now about 8 years old, always closes the squinting eye when looking at near objects, because of some interference with accurate vision of the other eye, and though he can not explain it, it is most probably due to the recognition of the false image of the misdirected eye, a diplopia. The refraction of the eyes is emmetropic; therefore, the only explanation of the squint is that of the macular lesion of the affected eye, and the latter permits itself to be dragged inward by the stronger internus muscle.

There are also other exceptional causes of strabismus but all of these together do not invalidate the foregoing teaching. They only place us on our guard in our investigations; perfect our methods; and make of us more accurate observers. A consideration of the etiology of strabismus convergens would be incomplete without paying homage to that master-mind of Donders, of Utrecht, who thirty-three years ago, in his immortal work: "Accommodation and Refraction of the Eye," gave to the medical world the first clear conception of the causation of convergent squint; stated that 77 per cent. of the cases were due to hypermetropia; and placed the proper value on the use of convex lenses for the correction of the anomaly.

II. ITS MANAGEMENT.

When considering the etiology of strabismus convergens we concluded that there were three quantitative degrees of hypermetropia that especially required our attention, and that the cases of medium amount (2–6 D.) of this anomaly furnished three-fourths of our cases of squint. The possessors of a low degree (up to 2 D.) of far sight, are often not seen in practice until the middle period of life, when near work becomes tedious and subjective eye symptoms force the patient to wear glasses some years earlier than the usual presbyopic time.

Those children who have the highest amount of hypermetropia (over 6 D.), are dismissed from school because they can not see the markings on the blackboard and appear mentally dull. They are advised to see an oculist, glasses are fitted and they return to their studies. What are we going to do with our young hypermetropes who squint? Estimate the amount of their error under atropin and give fully correcting glasses, to be worn constantly during the waking hours, together with the use, for a time, of atropin daily to annul accommodative efforts and break off the formed habit of over-convergence previously needful for accurate vision, especially of near objects. If we can demonstrate an amblyopia of the deviating eye, supposedly due to non-use, we stop using the atropin first in this eye, and advise[5] the practicing of its vision alone for a time, thus giving this eye an advantage for near use. Later stop using atropin in the good eye and still practice with the weaker eye, twice daily for an hour or more, the good eye being covered at the same time.

The amount of error is estimated usually by means of retinoscopy (skiascopy), this plan being more accurate than the ophthalmoscopic measurement, and even where our patient is able to read type, the subjective test is less reliable than by the first objective method mentioned.

The glasses given are changed as needed and are worn faithfully, until we are assured that they will not alone avail for the cure of the deviation, and until the patient is old enough for the operative procedure. In cases of supposedly spasmodic squint it is well to defer operative procedures indefinitely, also in cases of alternating strabismus, and in cases where repeated measurements give variable amounts of deviation, be slow to operate.

In squint cases where the error of refraction, on reexamination, is decreasing, and in families where strabismus has been known to continuously disappear, do not operate until after puberty or full growth of the eyeball. The correcting spectacles, without or with operation, must constantly be worn to avoid recurrence due to the still present hypermetropia. Now we have remaining the cases of squint where intracranial or retinal causes produce the deviation indirectly by the resultant poor vision. If operation is decided upon in these cases it is solely for the cosmetic result. Here we can not expect to institute what has never before been established, viz., binocular single vision. In fact, in those cases that we have still left as suitable for operation, we can not expect to regain this great desideratum—the aim of all of our surgical procedures—in more than 10 to 20 per cent. We may get parallelism in 50 per cent., and we expect satisfaction in 80 per cent., or, by our present methods, a success in practically all of our selected cases. That the subject of the operative management of strabismus is still unsettled in its entirety, is evident from the continued discussion of the subject in the journals and in the special medical gatherings throughout the world. Even as lately as the meeting of the Ninth International Medical Congress (Washington, D. C., 1887), several members admitted that the correction of strabismus was not a satisfactory operation.

---

[5] *Blindfolding the sound eye and practicing the deviating eye was* ninety years ago one of the successful methods of correcting strabismus, and Mackenzie quotes (Amer. Ed., 1855, p. [illegible]) the case of Professor Roux, who thus cured strabismus in himself of thirty five years' standing. Beer (loc cit.) was in most cases successful "by binding up the sound eye every day even for a couple of hours only."

The first operation on an ocular muscle was done by Stromeyer in 1838 on the cadaver (Mackenzie, p. 369, Amer. Ed. 1855). "Pauli was the first to attempt it on the living, but the eye was unsteady; he divided the conjunctiva but could not divide the muscle" (Mackenzie, pp. 369, 370).

Later, in 1839, Dieffenbach operated on a living patient, cutting through the belly of the muscle. The posterior half of the muscle then retracted, so that no reattachment to the eyeball could take place. The complete paralysis of the cut muscle was followed by a divergent squint. Such result was observed to be invariable after this method of operating, and the procedure fell into great disrepute (Fuchs, p. 710). Böhm then suggested a section of the tendon of the deviating muscle, and such method has been continued ever since.

Von Graafe improved the technique of the operation, showed how to increase and diminish the effect, and instead of cutting the tendon, when in the grasp of forceps, he introduced his hooks and the section was made on these. Both of the latter methods are still in use. The résult from the Dieffenbach operation was so disastrous that the subjects of it presented erial for further corrective procedures, and Jules rin, in 1849, operated on these cases of divergent it with the view of advancing the attachment of the cut internus toward the cornea. He dissected from the inner portion of the sclerotic all the superjacent structures—conjunctiva, Tenon's capsule, internus, and far back toward the equator of the eye. He then placed a thread *through* the sclerotic on the external side of the cornea, and by drawing on both ends of the thread he rotated the eyeball inward to the desired extent, and fastened the thread ends, by strips of plaster, to the skin of the nose. In this way it was hoped that a more anterior attachment of the severed internus would take place. The thread was left *in situ* several days. but it was observed to cause serious inflammation in some cases, now known to be due to a traumatic cyclitis, because of the depth of insertion and the location of the thread.

Now the ingenious von Graafe came to the rescue, and proposed the so-called *thread operation*, which differed from Guerin's plan only in that the internus was not severed from the sclerotic immediately at its insertion, but a short distance behind it, so that a stump of the tendon was still adherent to the sclera. Through this stump the thread was passed and the eyeball guyed in and fixed, as before, in the desired position.

Since then thread methods of advancement have been greatly improved, and several plans have been followed—some consisting of three threads, some of two threads, some where a single thread is advocated. They all agree in attaching the thread or threads directly to the severed tendon of the muscle to be advanced, and stitching the forward end or ends to the eyeball in front, where traction on the thread draws forward the muscle and tilts inward the eyeball to the requisite extent, and so retains the two fixed points for the necessary days required for the cicatrization of the wound at the site of the tendon of the advanced muscle.

From this history you will see that we have established two procedures, one of tenotomy of the insertion of the tendon of the internus in cases of convergent strabismus; the other of advancement of the retracted muscle subsequently to a former tenotomy of it, in order to correct the opposite deformity, a divergent strabismus. These operations on the internus tendon are equally applicable to that of the externus, though rarer; also to those of the other straight muscles of the eye—the superior and inferior recti—though operations on these tendons are still less frequently required.

We are considering a convergent squint and its correction, and we want to lessen the over-effect of this internus muscle on the deviated eyeball. As we have seen, when considering the etiology of squint, that this muscle usually possesses a superabundant strength, when compared with the often congenitally weak externus, and that owing to a continuation of the deviation a permanent shortening of the distance between the origin and insertion has occurred. Besides, its anterior attachment to the sclera is always further in front of the center of rotation of the eyeball than that of the less favored externus.

The indication is then plain; we must increase the distance between the origin and insertion of the internus muscle, or weaken its strength, or both, in order to destroy its over-effect on the deviated eyeball.

How are we going to do this? 1. By displacing backward the anterior attachment of its tendon to the required extent. In cases where the deviation does not exceed three millimeters, a careful section of the tendon of the internus at its insertion is usually sufficient to correct it. In cases of four to five millimeters, if tenotomy of the shortened internus insufficiently corrects, the teaching has been to free the lateral expansions of the tendons that are derived from the capsule of Tenon, where the muscle passes through the latter, near the equator of the eyeball. These connective tissue fibers on each side of the tendon are cut to the requisite extent. If the eye then fails to roll outward sufficiently, a guy suture is inserted vertically through the conjunctiva, just beyond the outer margin of the cornea, and one end passed through the outer commissure of the eyelids. The two ends are then tied, with traction sufficient to drag the eye outward to a correct position. This traction results in a displacement backward of the cut tendon, and the thread is left in from a few hours to two days.

Where the strabismus measures five to six millimeters, the cutting of one tendon is insufficient for correction without displacing backward the muscle so far that the resulting loss of motion inward impairs the future usefulness of the eye. when observing objects situated in the extreme nasal field of this eye. The operated eye then fails to follow the other eye, and binocular fixation does not occur. Hence, the operation effect has to be divided between the two eyes. The deviating eye is tenotomized in its internal rectus, and after waiting a couple of weeks the remaining squint is removed by a sufficient operation on the internus tendon of the other eye. Thus the inevitable loss of motion that follows all successful tenotomies is divided between the two eyes. Where the strabismic deviation reaches eight millimeters the last directions are carried out, except that the lateral expansions must also be invaded with the scissors, in order to get a sufficient result. When the deviation is over eight millimeters, the teaching has been, and still is in many quarters, to make a simultaneous and very free tenotomy on each internus, and if the effect, after healing, is still insufficient, to again cut the internus of the eye that retains the best motion inward. Sometimes this extreme procedure proves insufficient and both muscles have been tenotomized a second time, and such eyes may then possess a parallel position for distance, but too often their power of convergence is so reduced, that for near use they are a source of great trouble and anxiety to their possessor, if indeed they do not later give up the fight for binocular single vision, one eye making an associated movement while the other fixes—briefly, a divergent squint occurring as the final result of over-operation. The latter effect may occur at any time from one to two years after operation, and though often seen after excessive operative procedures, yet it occurs very frequently after ordinary and legitimate tenotomies. Unfortunately, we have no positive means of foretelling its occurrence in the latter cases. Tenotomy of the lateral ocular muscles is a very simple operation, so far as finding and cutting the tendons is concerned. Very little anatomic knowledge, steady hands, a forceps, scissors and, if you wish, a pair of hooks, a blepharostat and a solution of cocain, are all that are required. We can not foretell positively in any case the results we will accomplish by such cutting.

The first internus tendon I ever cut was in a boy of 14, and without the slightest immediate change in the direction of the eye. I inserted into the wound made the smaller von Graafe hook, and made excursions clear back to the equator of the eyeball, and laterally in both directions, thus breaking down and cutting all the loops of tendon and connective tissue brought up on the hook, but still the deviation remained unchanged. I was nonplused, and felt confused, for others were present, so I stopped, knowing that there were matters in squint that were either not in the text-books, or I had failed to read them. My case was not a paralytic squint. The boy disappeared, without a correction, and I went to further observation and soon saw the same thing occur in the practice of the best men, two of whom had one case each where, after a tenotomy of each internus, there was no effect, and one put on guy threads and the other stopped operating and said nothing. A second head of insertion uncut and far back is not a sufficient explanation in these cases, for often we can not find it after prolonged search. Paralysis of the externus is excluded, as the eyeball is rolled directly outward. A shortening of the superior and inferior recti muscles is the common cause that keeps the eye from rolling outward. For the latter reason, the backward displacement of the cut internus is also limited, and besides a tenotomy of it, we need an opposing force to the other shortened and uncut structures. We have mentioned a guy thread, but this cuts out and is of only temporary use, while it is a bungling method of correction.

2. When considering etiology, it was seen that the more posterior attachment of the externus tendon, together with the relative weakness of this muscle, placed it at a great disadvantage; besides, when the distance between its origin and insertion is increased by the deviation of the eye inward, in convergent squint, it can readily be seen that, next to the cutting of the shortened tendon of the internus, a strengthening of the effect of the externus on the eyeball ought to be accomplished. As a matter of physics let us shorten the distance between the origin and insertion of the externus by cutting its tendon at the sclera, removing two to four millimeters of it, and reattaching the remaining tendon as far forward on the sclera toward the cornea, as the requirements of the case demand.

These two operations—a careful tenotomy of the shortened internus, together with a simultaneous shortening and advancement of the externus—have scored a great advance in the more certainly beneficial results of strabismic operations.

This combined operation was first advocated only in cases of divergent squint, where a tenotomy of the externus alone never exceeds a correction of over three millimeters, and where such section is wholly insufficient for a satisfactory correction. Of late years, more especially under the able advocacy of Landolt, this procedure has been applied to convergent squint, and has grown in favor so rapidly that at present it promises to soon be the only procedure for the correction of squints of over three millimeters in extent. The results are positive and can be more accurately calculated, but in the cases where it is most used it is found necessary, for a thorough correction, to advance the externus of both eyes—not simultaneously, but on the second eye after an interval of two weeks or more.

The objections to tenotomy are its uncertainty of results, the opposite deformity occasionally occurring, and the loss of motion invariably following the successful correction of the deviation. These conditions are absent after advancement; in fact, the eyeball retains its position in the orbit, is directed permanently correct, and its motility is greatly improved.

Most modern ophthalmologists consider that tenotomy ought to be limited to cases of motor insufficiency, latent squint, and to the slighter actual deviations, but Landolt believes that in all these cases advancement offers greater advantages, and he claims that in his hands it has never caused an over-correction.

There are advocates of an advancement of the antagonistic muscle alone; the externus in convergent, and the internus in divergent squint, without a simultaneous tenotomy of the deviating muscle. There are others who believe in a partial tenotomy of the shortened tendon, leaving a few strands of the tendon proper at its upper and lower border, associated with an advancement of the antagonistic muscle, desiring to only temporarily weaken the deviating muscle until the advanced muscle gains a firm reattachment (Beard). In the two latter procedures an increase in motility of the operated eyeballs is very marked, but the certainties of full correction are less assured.

Modifications of the foregoing procedures, in different cases, are carried out according to the dictates of the various advocates, and no consensus of opinion has yet limited different methods to special conditions. One certainty is accomplished because of the better results achieved, viz., that the champions of advancement are increasing greatly, and the cases where tenotomy is alone required are rapidly disappearing from our observation.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

X.—ENGLISH SURGERY. JOHN HUNTER.

(*Continued from page 284.*)

Hunter had attained the height of his glory in the middle of the eighties. He enjoyed the confidence of the public, had a very large practice and made a sensation through a few operations. In spite of the mass of business in which he was involved, he showed himself equal to it all. In 1790 he assigned to Home, who at his request a few years previously had been substituted for him in St. George's Hospital, all lectures, because they cost him too much time, and he wished to put his writings in order. His health had also suffered a severe shock, so that he no longer went to patients at night, and he never operated without the assistance of another surgeon. He had no lack of external honors, having been made surgeon-extraordinary to the king, first surgeon general in the army, and inspector general of the military hospitals. He became a member of the Royal Society of Sciences in London and Gothenburg, of the Académie de Chirurgie and the Royal Society of Physicians in Paris, of the American Philosophical Society, of the College of Surgery in Ireland, and last of all a member of the Medico-Chirurgical Society in Edinburgh. Besides occasional attacks of the gout, during the last twenty years of his life he suffered much from angina pectoris. Often he saw everything aslant (which he declared, was caused by an excessive contraction of the oblique muscles of the eyes, which drew both eyes about thirty or forty degrees from their natural position); his memory became weaker, and the asthma grow worse. On Oct. 16, 1793, he went into St. George's Hospital become violently angry, and fell to the floor, dead. They found a defective valve, with enlargement of the aorta. Only a few of his oldest friends accompanied the body to the church of St. Martin in the Fields.

John Hunter was, as his brother-in-law relates, small and compact, but strong; his countenance animated and open, in later years contemplative. As a young man he was very lively and given to pleasures, later on account of a difficulty in his chest he could drink no wine, and for the last twenty years drank nothing but water. He needed little recreation; he slept only five hours. Passionate by nature and easily aroused, he was pacified only with difficulty. His mind was extraordinarily active and showed a natural disposition for investigation. His practice had grown but slowly at first, for his love of independence lead him rather to devote himself to his favorite pursuits, than to widen the sphere of his public activity. Only when his great talents attracted general attention did his income increase considerably and amounted in the last years of his life to five or six thousand pounds. But he valued money little, and devoted everything to collections and investigations, by which the interests of himself and family suffered. Very open hearted in private practice, he always expressed his opinion without reserve, but was at any time ready to acknowledge a mistake. An enemy to all deceit and falsehood, he, in going about, spoke almost too freely and often harshly of his colleagues, by which he made many enemies. History places little value upon such weaknesses of great men, but their contemporaries often have to suffer severely from them. If Hunter did not do justice to the merits of others, it was not due to envy nor jealousy, but to the conviction that surgery was still in its infancy and he himself only a beginner in it. Therefore, in his effort to perfect the science, he undervalued those whose activity did not equal his own.

When John Hunter, in the twentieth year of his life, went to England, where facts were valued most highly and practical effort everywhere prevailed, he began with admirable industry to make experiments and to collect observations. This was the most important feature of his life. His investigations included the whole animal kingdom, from the smallest insect to the elephant, in the course of which he dissected more than five hundred different species, and made a great number of discoveries. He found that bees do not collect the wax but secrete it; discovered the ability of the mollusks to absorb their shells, the true nature of the circulation of crustaceans and insects, the organs of hearing of the cephalopod, the semi-circular canal of the cetacean, the lymph glands of birds and the air cells in their bones. He wrote concerning the electric organ of the torpedo, the organs of hearing in fishes, the maw of the salmon, and on wall-fish. Young animals were fed with madder, and in that way the laws of growth and bone formation were ascertained. He furnished the information that the wolf, jackal and dog, belonged originally to one species, and by the incision of an ovary made researches in regard to the number of young. In the human body, he discovered the muscular membrane of the arteries and iris; he found that a few branches of the n. olfactorius came from fifteen cranial nerves; he traced the arteries of the pregnant uterus to the placenta, described the depression of the testes in the new-born child, by means of the gubernaculum called after him, and asserted the digestion of the stomach after death, through its own gastric juice. He also showed that the red corpuscles later form other constituents of the blood. Then he turned to the plant world and wrote on the power of plants and animals to generate heat; and there followed investigations in minerals and crystals. In short, Hunter wished to unite all branches of natural science, in order to advance from the simplest to the most highly developed forms; he asserted that nature observes a regularity even in her variations, and that under certain conditions a variation is a part of the law of nature.

His physiologic principle was "vital power," which held sway, even to the time of Johann Müller. The theory of the vitality of the blood did not originate with Hunter, for Harvey had already asserted it, but Hunter sought to give it a firm foundation and his opponents at that time were not able to expose the fallacy of this theory with sufficient reason. That this theory could have been held so long, came about as it so often happens, from the fact that the ideas of great men are so very seldom examined with attention, and tested. He said, "to conceive that the blood is endowed with life while it circulates, is to make the utmost demand upon the imagination; the difficulty arises from the fact that the blood is a fluid and we have not been accustomed to think of fluids as living. Disease manifests itself more clearly in the blood than in any other part of the organism, and all this is said to proceed from a dead animal fluid, upon which a disease of the solid parts makes such an impression! That is to attach too much importance to the solid parts and too little to the fluid. When one reflects upon all that concerns the blood, then the idea that it is living is not so difficult to grasp, and when he has once seized it, I can not conceive how one can think any other theory possible, so soon as one considers that all the parts are built up from the blood, that we grow by means of it, and that if it does not already possess life before this operation, it must receive it during the process of formation, since the parts, when they are once formed, possess life, and of that we are all agreed. William Hunter was the first to point out the fact that a callus is endowed with life as well as the bones. The vital principle of the blood, which is similar in its action to the vital principle of the solid parts, owes its existence to the same matter from which the latter is derived, namely the materia vitæ diffusa, which is equally diffused through all the solid and fluid parts." Hunter had an aversion to definitions, and instead of giving one for life, he stated its properties, saying that the first and simplest conception of life is, that it is the principle of self-maintenance and then the principle of activity. Though Haller has the credit of having first separated the human body into its anatomic elements and specified the physiologic characteristics of each, Hunter (who has left behind him ten folio volumes of physiologic notes) endeavored to apply these studies to pathology. The connection between physiology and pathology underlay all his theories; when he adduced the laws of life and applied them to the explanation of disease, he found a new method of inquiry.

In spite of his great accomplishments in physiology, the sick man was always to him the favorite object of investigation. They were accustomed in England to proceed by the induction method, while in Scotland the conclusions proceeded from general principles to particular cases; in Scotland a great logician was considered a great man, in England only when he had proven his position by experience. Buckle said that Scotland, where Hunter spent his youth, implanted in him the deductive method, and England, where he lived for forty years, gave him the inductive method. When his mind was divided between the two methods a certain obscurity marked not only his words, but also his thoughts. That was his error. Both methods are most clearly evident in pathology. With his inclination for deduction he endeavored, among other things, to introduce the idea that all diseases develop more readily on the skin than in the internal parts, by virtue of a latent impulse, which also impelled plants to approach the surface of the earth. Another deductive proposition was the following: "Since I regard every process in the organism as an action, whether it be general or local, it seems to me without doubt, that two different actions can not take place in the same constitution, or in the same part, at the same time. From this principle it follows that two different fevers could not appear in the same constitution at the same time, nor two local diseases in the same part." With this inclination of mind, Hunter roughly opposed the traditions of the English. However, a large part of his investigations were, as far as possible, inductive. He neglected no opportunity to make a dissection, anticipating that the progress of medical science would depend on the general introduction of dissection. He made pathologic anatomy at home in England and gave it an immediately practical direction, and was. therefore, perhaps even more influential than Morgagni's works.

He especially endeavored to make the knowledge which he gained of value in the perfecting of surgery. A large part of the surgical improvements which were introduced during the next decade after his death can be traced back to him; even his expressions were for a long time common in the English schools and exercised an influence upon the style of the new surgical books. The most important among his surgical works, which we will later enter upon more particularly, is "A Treatise on the Blood, Inflammation and Gunshot Wounds (1794). In this work, which, like all products of genius, exercised an inexpressible charm, there was, properly speaking, a new method of investigation in surgery laid down. The treatise on inflammation, which was first outlined in 1762 after the retaking of Belle Isle, and arranged from observations which Hunter had made during twelve years in London, was from that time forward considered by the public as his chief work. In the course of these investigations he frequently allowed himself digressions which have a remote connection with the main subject, while he perplexes the reader by his lack of form. But a part of his obscurity is explained by the fact, that at that time he was often sick and depressed, and he died while engaged upon the complete correction of the work. In order to offer as complete a book as possible, he had long delayed the publication of it, and hoped that it would enable others to work upon a subject of which they had previously known nothing at all. He, himself, regarded this treatise as a new building put together out of crude materials, whose defects were not unknown to him. Further, we owe to Hunter the first knowledge of phlebitis (1793), investigations in varices, aneurysms and with this the ligature of the arteries above the sac (1785), the forerunners of subcutaneous operations, clear-sighted treatises on syphilis (1786), the "Structure and Disease of the Teeth" (1771), intussusception, anuresis, etc. He was the only one who comprehended the first ideas of vaccination of his pupil Jenner, and mentioned them in his lectures as a matter that deserved further research. When his operations failed, he sought for the causes with the utmost care, and in this way discovered many imperfections. The successful extirpation of exceedingly large tumors in the neck testifies to his operative skill; in one case, one of the best surgeons in England had declared that only a fool or a lunatic would venture to cut out the tumor. His skill in diagnosis, for that time very great, was shown, among other ways, in a case of a gunshot wound in the abdomen, where the others ascribed the tension of the abdomen to the flow of blood, while he convinced himself by "percussion," that air was the cause of it (1783). He also diagnosed an organic defect of the heart and found, on dissection, that the valve of the aorta was thicker, harder and very much contracted; the symptoms explained this to him, since at every contraction the blood must flow back into the ventricle. His complete works were printed by Palmer in 1834.

Hunter's greatness was not recognized by his contemporaries. He valued ideas for their own value, quite independent of all other considerations, for which the English had no inclination so long as no definite result appeared. Shrewd, but short-sighted, they were unable to comprehend [illegible] -reaching ulations. According to their opinion Hunter was little more than an innovator and fanatic, and even his practical improvements met but a cold reception. A secret antipathy to minds which far surpass our own everywhere lurks in human nature. The epoch-making work on inflammation, in which the subtlest and most difficult subjects in nature were treated, could gain no popularity for Hunter, because there were so few physicians who were able to follow him on this path. "The great Scotchman, thrown among a people whose mental habits were so unequal to his own, had," as Abernethy says, "a solitary and comfortless place by reason of his transcendency." They so little understood him, that during the four years when he lectured in London on anatomy and surgery, his hearers numbered twenty. If his own countrymen did not appreciate Hunter's greatness, what wonder that the same was true in Germany! A. G. Richter considered that in the work on the blood and inflammation, which did not reach his expectations, Hunter was, indeed, a clear-sighted observer with many new ideas; but he found that experience was often strained in order to conform it to theories. He had proven himself an excellent master of the art of expanding really useful, practical matters into a mass of empty theories, and of so analyzing every-day affairs that they became quite unrecognizable and were readily regarded as something altogether new. He could not write concisely and his prolixity and repetitions would tire even the most patient reader; he showed also, with his vigorous imagination, a great effort to present singularities. Richter would not contradict his experience with phlebitis, but he had never seen anything which seemed to confirm it, and did not consider it proven. But he had the greatest appreciation of the works on the teeth and on syphilis, although here, too, it seemed to him that Hunter had a great love for singularities, in that he often contradicted himself. Baldinger found the chapter on anuresis paradoxic. The translator, Hebenstreit, likewise emphasized the tendency to paradoxic statements; and found a reason for the lack of connection in the fact that Hunter had not enjoyed a liberal education in his youth, and only became a writer late in life(!). The article on the digestion of the stomach Tode considered a droll dream, and hoped that the English devisers of theories would gradually protect us from the prevalent anglomania. His work on the teeth was horribly dry and much in it was old; and for heaven's sake, let no one dare to confuse John Hunter with the celebrated William, for the former was a veritable Nimrod in hypotheses, as is well known. John Hunter was too far ahead of his time.

Only in passing will we cast a glance at the *surgeons in other foreign countries*, since most of them were greatly inferior to the French and English, and being little or not at all known in Germany, could not in the least exercise an equal influence on German surgery.

About the middle of the century a more active life began in the northern countries; they built hospitals and lying-in houses. *Sweden* at that time possessed the "northern Desault" in *Olof Acrel*, professor in Stockholm. Trained in Paris and in the French army, he first brought scientific surgery into his fatherland, and did an extraordinary amount for the improvement of the hospitals whose director-general he was. His "Surgical Cases" (1775), into which a large experience is gathered, was the first fruit of the new hospitals in Stockholm. He banished excessive warmth from the wards and strenuously opposed the many superfluous instruments, and the misuse of salves and plasters. *Bierchen* became known through his researches in cancer, wherein he sought to establish the diagnosis of scrofula and syphilis; *Martin* was known through his thermometric measurements; *Schutzer* and the oculist *Odhelius* may be mentioned.

Denmark was not backward. Copenhagen built its Friedrich's Hospital. A society of physicians and surgeons was organized in 1772, under Tode, which, elevated to a royal society, began to publish the "Soc. med. Havniensis Collect." Although a surgeon at a salary of 150 thalers was maintained at that time in each district of three to six (German) miles, yet the standing of the profession was low, and it is related as something extraordinary that a Count von Reventlow made the surgeon of his county his physician, entertained him at his table and at his social parties. King Christian VII. took the most important step in the advancement of surgery when he founded a Royal Academy of Surgery in Copenhagen in 1785, in order to train better surgeons for the country and the army. They took the new academy in Vienna as a model, and here also, as was the case in Vienna, they involved themselves in a quarrel with the sorely offended physicians, which was continued for several years, and on the part of the surgeons in a very stormy manner. The academy was independent of the university and of the collegium medicum; its professors (three ordinary and four reserve surgeons) enjoyed the same rank as the university teachers and belonged to number eight of the fifth class, where they stood on a level with the gentlemen, between major and captain of horse. The lectures were given free, and in the Danish and German languages. The most eminent Danish surgeon was *Callisen*. He had risen from the barber shop and had served as steward and in Friedrich's Hospital, had then studied in France and England for several years, and had finally become professor, chief surgeon of the Danish fleet and director-general of the academy. Beloved as a teacher and popular as a practitioner, he deserves great credit for improvement in the medical system, and with his "Institutes and Principles" (a systematic treatment of surgery), won much applause. The learned *Heuermann* wrote a good manual on operating, and Professor *Scheel* a great work on the transfusion of blood and injection of drugs, giving his own experiments.

The time of the great Boerhaave had aroused a general scientific interest in *Holland*, and had brought about a more intimate connection between surgery and medicine than was the case in other countries. Therefore, the best Dutch surgeons of the seventeenth century were at the same time good physicians, and showed more interest in the pathologic bearing in surgery than in the mechanical part. For the rest, even until the middle of the last century, the same altercations between physicians and surgeons as to the limits of their respective departments took place, as in Germany and France. The Dutch authorities decreed, among other things, that no physician, but surgeons alone, should practice obstetrics. Along with the anatomist Albinus, above all others ranked the genial *Peter Camper* (1722–1789), who was equally celebrated as an anatomist and physiologist and as a surgeon. At school, he employed his leisure time with architecture, optics, the turner's trade and cabinet-making, and after completing his studies, became on the same day Doctor of Medicine and Doctor of Philosophy. Repeated travels to England, France, Switzerland, and Germany brought him in contact with the most illustrious men of his time. In 1750 he first became professor in Franecker, then engaged in anatomy and surgery in Amsterdam, later in Gröningen, where besides these sciences he taught botany and medicine, but between his courses always went back to his estate in the country. Finally he settled in The Hague, where as a common councilman he died. Camper showed unlimited intellectual penetration; he was a master in drawing, painting in oils, copper engraving, turning, wood carving, and to all this he added a great knowledge of mathematics. When the war in Holland incited him to a study of fortifications, the Dutch canals were strengthened against the sea according to his plans. He also mastered the literature of every department of knowledge, especially the history of art, and was acquainted with both ancient and modern languages. He was a patriot in the noblest sense, was always ready for pleasure. and on the whole a very amiable man. Camper's scientific activity covered all branches of natural science, especially anatomy and zoology, in which, for example, he spared no expense to have a rhinoceros brought from Africa or a whale's head from Greenland, in order to study the anatomy of the hearing organ. His most important works in surgery were his "Demonstr. anat. pathol." (2 Vols, 1760–1762). He wrote on the diseases of the arm and pelvis, separation of the os pubis, cancer of the breast, lithotomy, fistula of the anus, prolapsus of the anus, bone callus, causes of lameness in children, fracture of the patella and of the olecranon, and congenital hernia, and made drawings of intestinal rupture. Few scholars have written so many prize essays as he; the Académie de Chirurgie in Paris five times awarded him a gold medal for his works on the misuse of salves and plasters, the best form of truss, the influence on surgical diseases of different kinds of air and of waking and sleeping. He wrote an original work on the best shape of shoes (1781), which showed the anatomic disadvantages of a high heel and was translated into various languages. There was no other Dutchman who approached Camper. *Van Gesscher* defended the necessity of amputation against Bilguer, and wrote on curvature of the spine. Professor *Bonn* in Amsterdam wrote on callus, luxations, bladder incisions (which he recommended to be made above the os pubis), and was also the author of "de continuationibus membranarum," from which Bichat borrowed a great deal, word for word, without giving credit. *Van Der Haar*, and *Ten Haaff* the ship surgeon, and *Van Wy* the lithotomist of Amsterdam, should be mentioned.

In *Italy* the last century produced a few good surgeons, but no epoch-making ones, until the last two decades, when A. Scarpa taught. When in the middle of the century the Italian language was so popular in protestant Germany that students in Halle had their theses printed in Italian under the direction of their language teacher, medical and surgical writings began also to be accessible through translations ("Eschenbach's Choice of Best Essays," 1783, "Kühn & Weigel's Bibliotheque," 1793). To the Italians as well as to the Germans of that time Paris and London were the El Dorado of all science. Among those who are still remembered was *Guattani* in Rome, who through his monograph on aneurysms ("De Externis Aneur." 1772) is erroneously regarded as the actual author of indirect compression (see Leber); he wrote the first accurate introduction to esophagotomy, giving experiments made on animals. The name of *Vacca Berlinghieri*, director of the surgical clinic of Pisa, is attached to this operation through the discovery of a special knife. Professor *Bertrandi* deserves credit for the reform of medical study in the Sardinian States; he wrote a manual on operating. In operations he laid stress upon accident, which sometimes made the most difficult ones a success and the simplest a failure. In Naples Professor *Cotunni* discovered the water passages in the interior of the ear (1761), gave exudation of the lymph in the walls of the N. ischiadicus, or the N. cruralis as the cause of ischias and recommended, accordingly, a strong vesicant along the nerve (1764). *Pajola* was considered a skilful lithotomist in Venice, as was also the Papal body-surgeon, *Flajani* in Sassia, whose collection of bladder-stones was one of the finest in Europe. In Florence lived *Benevoli*, *Palucci* (later in Vienna), *Cavallini* and *A. Nannoni*, who introduced a milder and less painful treatment of surgical diseases into Italy (1761), and also contended sharply against the abuse of salves and plasters. In the hospital in Milan worked *Paletta*, *Monteggia* and *Moscati*, later body-physician of Viceroy Eugene, and who became known through his assertion that man was intended to walk upon four feet. Vrolik in Amsterdam wrote a special dissertation to combat this evolution view. *Nessi* was trained in Pavia and was the author of a handbook on surgery, translated into German; and Pavia produced the most famous of all the Italians, *Anton Scarpa.* He was a pupil and assistant of Morgagni when the latter became blind; he was professor of anatomy and surgery in Modena and after 1784 in Pavia, where he established a surgical clinic. Napoleon, as king of Italy, appointed him body-surgeon and until 1812 he conducted the clinic; then on account of weakness of sight, being otherwise very vigorous (which he attributed to hunting), he retired. He died highly honored at the age of 85 in the year 1832. His greatest service was the development of surgical anatomy, which gave a characteristic stamp to all his works; these were provided with the most excellent drawings. We owe to him a so-called boot for clubfoot (with which the patient could walk, 1803), some excellent works on aneurysms (1804), hernia (1809) and diseases of the eye.

The most important occurrence in *Spain* was the founding of an academy of medicine in Madrid (1732) and of a separate college of surgeons (1741). At the end of the century there were sixteen medical and three surgical schools (Madrid, Barcelona and Cadiz). The study of medicine, for which no great preparatory knowlege was demanded, was mostly theoretic; the professors lectured and were commanded by the Castilian council to expound the institutions of Boerhaave. After a surprisingly easy doctor's examination a still further examination in Madrid, costing sixty thalers, was required for permission to practice. A supreme court placed over all Spanish physicians ruled with a despotism which debased their position; without assigning reasons it imposed fines and revoked the license to practice. The consequence was that only people from the lower classes, without means or education, studied medicine. Nevertheless, the number of physicians was very large: every village possessed a young Æsculapius (in Madrid, with 160,000 inhabitants, there were 135) so that almost all were poor and very few could support their families. Frequently they went as beggars, on foot, from place to place and begged at the doors of monasteries for some soup and a little alms. Under such conditions it could be no great triumph for the surgeons when they, through their influence at court, obtained political equality with the physicians made evident externally by being allowed the Spanish cockade and lace-trimmed clothes and receiving military rank. In 1795 a medical school was established in Madrid with better principles of instruction and entrance was made dependent upon a better elementary education. From that time on everyone who wished to practice in Madrid had to be a doctor and pay 300 thalers. One of the most distinguished among the Spanish surgeons, who were chiefly educated in the French schools (des Nähere bei Ullersberger, *Deutsche Ztschr. f. Chir.*, ii, 2[illegible]3, 1873), was *Anton de Gimbernat*, who first discovered (1793) the cause of the strangulation of the crural rupture in the part of the crural arch called after him.

(To be continued.)

PRACTICAL NOTES.

Congenital Teeth, according to Dr. Ballantyne of Edinburgh, Scotland, as being ill developed and serving no normal purpose in the economy, are best removed soon after birth. These exceptions are exceedingly rare conditions, for out of Magitat's 500 cases in which the eruption of the first tooth was noted, in only 1 case were there teeth at birth. Further, it is recorded that out of 17,578 new-born infants at the Paris Maternity, in ten consecutive years, only 3 had teeth, or not much more than 1 in 6,000. These teeth, as may be foreseen, have little or no significance as regards the bodily or mental vigor of the infant carrying them. Certainly we may add they are not stigmata of a degeneration into savagery and are not to be regarded as freaks of development. Probably Shakespeare had much to do with fixing the superstition of a monstrosity in the popular mind by one of his best-known dramas.

An Epidemic of Infantile Paralysis.—Dr. W. Pasteur of London, before the Clinical Society of that city, read a paper on an epidemic of infantile paralysis occurring among children of the same family. The epidemic was limited to this household. Every one of the seven children in the family were attacked in rapid succession, within the space of three weeks, with fever of moderate severity, accompanied by severe headache. In three of the children, aged 11, 9 and 5 years respectively, paralytic symptoms supervened within seven days of the commencement of illness. The type of paralysis varied in the different cases. In one there was flaccid paralysis of the left arm; in another right hemiplegia with marked and persistent muscular rigidity of the arm and the leg, with more transient paralysis of the face and soft palate on the same side; while, in the third case, there was paralysis with rigidity limited to the left lower limb. In two more the primary fever was followed by tremors lasting a few days, while in the remaining two the primary fever was not followed by any nervous disturbance. As regards the cause of the outbreak, it was possible to exclude the acute exanthemata, diphtheria and influenza. The points of resemblance to infantile paralysis were held to justify the diagnosis in spite of the remarkable characters of the paralysis. The cases prove that a poison giving rise in one instance to a paralysis indistinguishable from the acute atrophic paralysis of childhood is also able to determine lesions in other parts of the nervous system. They further strongly confirm the growing impression that infantile paralysis is an acute infective disease.

Acetanilid and Boric Acid as a Surgical Dressing.—Dr. Fallas writes (*Medical News*) that he had been led to seek for a combination with acetanild which would fully inhibit suppuration. He first tried boric acid, acetanilid and carbolic acid, but the powders were not sufficiently absorptive, and the compound was too moist and pasty. After many trials he used this: Powdered acetanilid, 48 per cent.; powdered boric acid, 15 per cent.; powdered starch, finely sifted, 35 per cent.; carbolic acid, liquid, 2 per cent. This compound, though slightly moist and adhesive, has all the effect of a dry dressing; in fact, upon a wound it is, or becomes, perfectly dry. Its absolute comfort leaves nothing to be desired; under its use there is not from first to last the least discomfort, except a momentary smarting on the first application, too trivial to be worth mentioning. The most exquisitely sensitive sore can in a few days be handled with impunity. There is no odor, even of the carbolic acid. It absolutely inhibits suppuration where it can reach the wound surface, and it checks and quickly abolishes suppuration if that be already present. The powder should be changed twice a day, as long as there is a discharge to moisten it; soon, however, the wound becomes absolutely dry, and the powder may be left undisturbed for many days, and will still be found as dry as when applied, unless there is a pocket from which pus may come. Cicatrization is rapid and satisfactory. Obviously, this powder would be unsuitable for introduction into a cavity, unless it was intended that the cavity should granulate from the bottom; and in that case the possibility of easy removal of the masses formed by the pus soaking into the powder before the wound becomes dry, should be considered. On an accessible granulating surface and upon a sutured wound, it comes very near to being a perfect dressing.

Placenta Previa at the German Congress of Gynecology.—This subject was the question of the day at the recent Congress and Kustner stated that he had delivered eleven living infants out of sixteen cases of placenta previa treated with the colpeurynter. He adds that 500 grams are enough to distend it, and hoped that some instrument would be devised soon to perforate a "central" placenta without injury to the large vessels or to the child. Several observations were described which prove the existence of a cervical placenta previa. Schatz observed that if there is a connection between placenta previa and endometritis, as seems probable, the latter should receive careful treatment whenever it occurs, and the former would then be less frequent. If it could be diagnosed in the early stages, then artificial abortion and curettement would be indicated, but it is scarcely possible to diagnose it at first, although with skill and experience it can be detected at the third month. He orders repose, morphin and viburnum prunifolium, in case of hemorrhage during the latter months, continuing the last a long while. If hemorrhage persists, he tampons the vagina until able to practice the Braxton Hicks version. He does not rupture the bag of waters until the head is engaged in the pelvis or podalic version can be effected. He has not found the colpeurynter useful except after the rupture, when he inserted it into the uterus, with gentle traction on the tube. He tampons the uterus finally, if it does not contract sufficiently. Hofmeier remarked in his address that persistence of the hemorrhage after rupture of the waters is an indication in favor of a normal placenta prematurely detached. He disproves of leaving the vagina tamponed several days, and ruptures the bag as soon as labor has commenced, as the fetus pressing against the cervix will compress the bleeding parts. He follows it immediately with combined version and drawing down the feet. He recommended also the Braxton Hicks method, using the colpeurynter if the dilation is insufficient. The strength of the patient must be sustained with subcutaneous injections of salt solution, ether, or camphorated oil, injections of stimulants, etc. When impossible to reach the edge of the placenta, rupture of the bag and podalic version by tearing the chorion and amnion is the only resource. The child has usually to be sacrificed, but there are scarcely any means to save it in these conditions.

The Value of an Exclusively Meat Diet in Certain Cases of Chronic Gout.—At a recent meeting of the Medical Society of London, Armstrong (*British Medical Journal*, May 1, 1897) related that during the last few years he had given trial in various cases of gouty arthritis and recurrent renal calculi to a method of treatment based on the prolonged administration of only red meat and hot water. Very marked improvement had resulted, which had persisted in spite of gradual return to an ordinary dietary. His own observations on auto-intoxication in relation to the causation of gout and rheumatoid arthritis, had led him to believe that it is the complex chemic changes brought about by the admixture of red meats with carbohydrates and sugar that causes the excessive formation of uric acid. His plan is to give the patient a daily allowance of from one to four pounds of lean beefsteak, minced and cooked in various ways, the patient drinking from one to five pints of hot water, and avoiding all starchy, saccharin and fermentative articles of food. The effects observed are rapid diminution in abdominal girth, loss of fat and flabby tissue, increase in the quantity, and ultimate disappearance of urates, alkaloids and toxins from the urine. The joint-swelling greatly diminished, the aching and pain became much lessened and the mobility of the joints was considerably increased. The capacity for work, mental and bodily, was enhanced and the symptoms of mal-digestion and disassimilation disappeared. This treatment is indicated in obstinate chronic gouty arthritis, in recurrent uric acid calculi, in frequent and intractable migraine, and in cases of persisent gouty dyspepsia. It has proved especially useful in the presence of symptoms of amylaceous and intestinal dyspepsia and of excessive formation of hydrogen sulphid, urates, indican, skatol, creosol and other toxins. The carbohydrates, by their affinity for oxygen, interfere with the due oxidation of the tissues. Under the plan of treatment proposed, digestion is more complete and the processes of fermentation and putrefaction are kept within narrower limits, oxidation being more perfect and less waste being consequently left in the system. Whatever poisonous matters remain in the system are readily eliminated by the taking of the hot water, which also flushes the stomach, liver and kidneys. The treatment is irksome and trying, and must of necessity be carried out with great strictness; therefore its use should be confined to the more difficult cases. It should be prescribed but rarely and then only under the most careful supervision in cases in which the heart or kidneys are diseased. Used with due care it is a most efficient and brilliant addition to the therapeutic measures. In the discussion Haig admitted that certain cases of gout are benefited by a meat diet, as a result of its stimulating qualities. When it fails to act as a stimulant it is likely to prove dangerous.

Case of Fibrinuria.—The *British Medical Journal* quotes Dr. A. Klein's report, in a Vienna journal, of one of these rare cases in which fibrinous clots are passed in urine. Klein first analyzes the four recorded cases that had been previously recorded regarding this condition. The author's case was that of a male, aged 52 years, who had been ill for fifteen months with cough, headache and dyspnea on exertion, to which had recently been added swelling of the extremities and rigors. Examination led to the diagnosis of Bright's disease; the urine was acid, of specific gravity 1013, and contained a large quantity of albumin, with numerous hyaline and epithelial casts. Treatment consisted in hot baths and milk diet, and the patient improved considerably, the edema almost completely disappearing. Ten days after admission it was noticed that the urine, which was slightly alkaline, contained a large number of grayish-white clots, some rounded and others flattened, and varying in length from half an inch to four inches; some were as much as two inches thick. These, if allowed to stand, settled to the bottom, and the supernatant urine sometimes showed a further curious phenomenon in the shape of fine threads, which formed a network extending throughout the fluid. On shaking, this became detached from the sides of the vessels and formed a well marked clot; the urine had thus clotted just like a serous fluid. The amount of deposit remained constant, except just before a rigor, when it diminished to return to its former amount with the subsidence of the temperature. If the clot were allowed to remain in the urine for a few hours it disappeared entirely, probably by a sort of process of self-digestion. Chemic examination proved the clot to be composed of fibrin. The urine from which it was deposited showed, as compared with that at other times, alkalinity, much diminution in solid content, an especially minute amount of phosphates, but an enormous quantity of albumin. There could be no doubt as to the renal origin of the fibrin, but it was very hard to define its pathologic cause. Evidences of nephrolithiasis, kidney abscess, etc., which had been present in former cases were here wanting; nor did hematuria ever appear. Klein attributes the coagulation to the alkaline reaction, the large quantity of albumin, and the almost complete absence of phosphates; it bore also, no doubt, some relation to the sudden rigors and rises of temperature. Some time after the completion of the experiments the patient became worse and died; the kidneys were found to be in a condition of amyloid degeneration, and their tubules contained hyaline masses and threads giving Weigert's reaction for fibrin. Klein adds the notes of analyses of two other kinds of clots. The one was found in the urine in a case of cystitis; it consisted of a nucleo-albumin inclosed in a capsule of mucin. The other was a cast from a patient suffering from plastic bronchitis, and this failed to give the fibrin reaction either in bulk or in section; it consisted of mucin, and contained large colonies of diplococci.

A Rapid Method of Fixing and Staining Blood-Films.—Gulland (*British Medical Journal*, March 13, 1897, p. 652) describes briefly a method of making permanent microscopic preparations of blood that he has learned to follow and that gives accurate fixation, is rapid in execution and is sufficiently flexible to avoid the spoiling of preparations in consequence of even considerable deviations from the exact method. A small drop of blood, drawn in the usual way, taken up on the center of a cover-glass held with forceps and distributed evenly between that and another cover. The utmost care must be taken to avoid all pressure, as the after-appearance of the red corpuscles depends almost entirely on the way in which this maneuver is carried out. The covers are then gently and rapidly slid off one another and dropped, with the wet side downward, into the fixing solution, which consists of absolute alcohol saturated with eosin 25 c.c., pure ether 25 c.c., mercuric chlorid in alcohol absolute (2 gm. to 10 c.c.) 5 drops (more or less). The quantity required for use at one time, which may be from 5 to 10 c.c. for four cover glasses, should be poured into a wide-mouthed bottle or a flat dish, and may be used several times over if it be preserved from evaporation. The three liquids may be kept in separate bottles and be combined in the required proportions when needed. The fixation of the elements is practically instantaneous, but the cover-glasses should be allowed to remain in the solution for at least three or four minutes, in order to fix the film to the cover. They are then taken from the solution with forceps and washed rapidly but thoroughly by waving them to and fro in a small basin of water. They are then stained for one minute (not longer) in a saturated watery solution of methylene-blue and again rapidly washed in water. Next, they are quickly dehydrated in absolute alcohol (which at the same time removes the excess of methylene-blue), cleared in xylol and mounted in xylol balsam on a slide. The whole process need not occupy more than six or seven minutes, although any portion of it may be prolonged without injury to the specimen. The fixation may be continued for twenty four hours and the washing for the same time, but if the staining with methylene-blue be prolonged for more than a minute or two it becomes necessary to use an inconveniently large amount of absolute alcohol to remove the excess of the stain, and the eosin may be washed out at the same time. The red corpuscles are stained pink, the nuclei a deep blue, the bodies of the leucocytes various shades of pink; the eosinophile and the basophile granules in the leucocytes are well brought out; the blood-plates are stained a fainter blue than the nuclei; and organisms also are well stained. Any other stain that is soluble in alcohol and is not precipitated by mercuric chlorid may be used instead of eosin; and the stain may be omitted from the fixative altogether, so that the cover-glass after fixation in the alcohol-ether-mercuric-chlorid solution may be stained in any way that is desired. The method is also useful for fixing pus, sputum and anything else that may be spread in a film; only with these it is advisable to prolong the fixation.

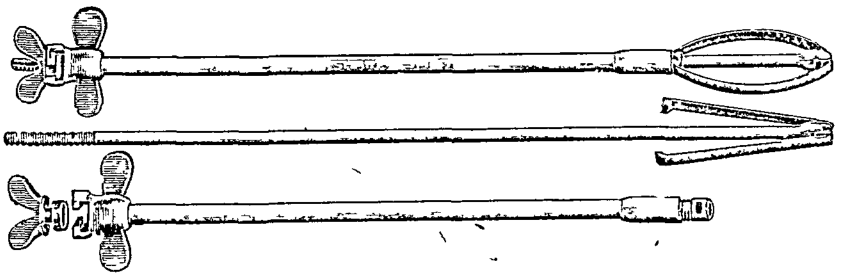
Gunshot Wounds of the Chest with Penetration of the Lung; Extraction of Bullets; Recovery.—Musgrove (*British Medical Journal*, May 29, 1897, p. 1342) has reported the case of a man, 26 years old, who was found in a field in a state of collapse, bleeding profusely from the front of the chest. He was conscious and stated that five and a half hours before he had fired two bullets from a revolver into his chest, with the intention of killing himself. On removing the clothes saturated with blood, after transporting the man to his home, two circular wounds were found in the precordium, one over the fourth rib and the other in the fourth interspace, both blackened with gunpowder and both bleeding profusely. From the lower wound also air was escaping at each expiration, whilst there was emphysema of the cellular tissues on the left side, extending up into the neck and down to the level of the lower ribs. On probing these wounds the track of the upper one was found to pass outward along the rib, while that of the lower led almost directly backward, with a slight inclination to the left. The probe was passed along the track of the lower wound for six inches backward through the cavity of the chest. No bullet could be felt in either of the wounds. On account of the weak condition of the patient no further search was possible until a little later, when by turning the patient upon his right side and making incisions along the inner border of the scapula and using a probe the two bullets were found, the one corresponding to the upper wound in front lying in contact with the outer aspect of the fourth rib, along which it had evidently run, while the other lay projecting between two ribs and had to be dragged forcibly out by forceps, along with a piece of bone (apparently from the anterior part of the fourth rib) with which there were entangled fragments of wool, corresponding in color and texture to those of his undershirt. These bullets were of large size and had sharp projecting spiral spurs on their surface, evidently due to their having been too large for the bore of the revolver. As ether and chloroform were inadmissible, owing to the patient's condition, local anesthesia was effected by means of ethyl chlorid spray and hypodermic injection of cocain. The incisions were afterward packed with boric acid lint soaked in carbolic lotion. For three days the respirations were rapid, but the pyrexia was slight. On the second day an attack of severe dyspnea occurred. There was no expectoration or cough until the fourth day, when a small quantity of plum colored sputum was brought up and also once or twice daily until the tenth day. On the first appearance of the sputum the odor of the breath became offensive, but it became normal again in the course of a few days under the use of a creosote spray. No lung-tissue was found in the sputum. The incisions in the back were dressed daily, being packed with lint as at first. From the fourth to the sixth day a rubber drainage-tube was substituted, but was subsequently discarded for the former. On about the fifth day dulness and other signs of pleuritic effusion on the left side appeared, and on the twenty-third day of the illness, when this dulness had risen to the level of the spine of the scapula an exploratory trocar was introduced and four ounces of transparent blood-stained fluid withdrawn. On the repetition of this operation a week later no fluid could be obtained, but the costal pleura was felt to be enormously thickened. The dulness cleared up, leaving a slight impairment of the percussion note. The posterior incisions healed up in the course of a month, and several weeks later the patient was able to take a long walk without dyspnea or fatigue.

NEW INSTRUMENTS.

A NEW CURETTE.

BY COURTNEY L. SMITH, M.D.
AURORA, ILL.

Curetting the uterus for endometritis, subinvolution, retained products of conception, etc., has come to be a very common operation. It is deservedly recognized as a valuable procedure in these conditions, and accomplishes speedily what local treatment or the exhibition of medicines can not. It needs no argument to prove that unless curetting is thoroughly done, and the material scraped off is removed from the cavity of the uterus, the operation is apt to do more harm than good. I think the experience of the majority of physicians will bear me out in the statement that there is a large element of uncertainty in performing curettage with the ordinary spoon curette. We are never sure, in using this instrument, that we have not neglected to reach some portion of the mucous surface, or that some shreds of tissue have not been left behind to cause trouble.



The instrument shown in the annexed cut was designed to overcome these objections and adds much to the ease of performance and the safety of the operation. The main part of the instrument consists of two cutting or scraping blades, which can be stretched flat or bowed out in the form of an ellipse by a rod and screw. After dilatation of the cervix in the usual way by a branched dilator, the closed curette is readily slipped up to the fundus. The screw is now turned, thereby separating the scraping blades and drawing the stretched membrane tight down upon them. Rotation of the instrument removes the diseased tissue, much or little being scraped away as we desire. A backward turn of the screw straightens the blades and the instrument is withdrawn.

An examination will now show that the space between the blades is filled with shreds of tissue brought out with the instrument. A plunge in sterilized water cleanses it, it is again introduced slightly dilated and given a turn or two and drawn out with the remaining shreds. The products of the operation are now removed with the exception of a slight amount of blood and small clots, which are readily washed out by the irrigator.

The advantages claimed for the instrument are the following:

1. It is easily introduced and manipulated.
2. Every portion of the uterine mucosa is curetted as the instrument is revolved.
3. As it is withdrawn all shreds of tissue are removed with it. And
4. There being no sharp angles or points to go through softened tissues, there is no danger of perforating the uterine wall.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 14, 1897.

THE ANTIVIVISECTIONISTS AND THEIR LITTLE BILL.

Whether or not we may console ourselves with the thought that many of those posing as antivivisectionists are degenerates or perverts, we must remember that Senate Bill No. 1063 is still on the calendar and will undoubtedly be taken up at the next session. Missionary work must be done during the recess of Congress. Here the general practitioner may be of infinite service in giving his Senators and Representatives, wherever they are found, his opinion why the bill should not become a law. The infamous attempt to stifle physiologic experiments by the enactment of the bill can be defeated, if the profession will see to it that each Senator and Member of the House of Representatives is furnished with the necessary reasons why the measure should not pass.

Modern medical science rests almost exclusively for its facts upon animal experimentation; without it the beneficent effects of vaccination would have been unknown, physiology would have been a collection of fables, and bacteriology still in the future. The great practical benefit to mankind through the advanced state of knowledge in medicine and surgery should be made clear to our legislators, and the effect of passing crippling laws should be clearly explained. The bill can not be beaten by making faces at the misguided perverts or even by pointing out their lack of mental equilibrium; we must demonstrate fully and conclusively the evils that will flow from the enactment of a law stopping animal experimentation; that man who is a little lower than the angels, is yet immensely superior to the lower animals, and that the same law of self-preservation that causes us to slay and eat, causes the humanitarian to use animals to work out problems for the prevention of the disease, through development of human wisdom, for the preservation of the human species.

The higher value placed upon human life is the glory of modern civilization, and notwithstanding the existing necessity for enslavement and use of the lower animals we are far kinder to them than the ancients. The ancients, who roasted their enemies, tore them limb from limb, harrowed them with "harrows of iron," tortured them with fire, made them beasts of burden when great public works were to be erected, were even more cruel and careless of the lives of animals. If they occasionally worshiped an animal, it was on account of some particular benefit conferred, or dread of evil to come, a habit which JUVENAL set forth with his pungent sarcasm.

> The serpent-eating ibis these inshrine;
> Those think the crocodile alone divine;
> Then in another place you may behold
> The statue of a monkey shine with gold.
> Here men some monstrous fish's aid implore,
> And there whole towns a grinning dog adore.
>
> —JUV. XV. 2.

Nearly all that was known of anatomy in the early times was obtained by dissection of living and dead animals. By command of ALEXANDER the Great, ARISTOTLE made regular vivisections on animals, and later PTOLEMY PHILADELPHUS, apparently to outdo ALEXANDER, gave HEROPHILUS and ERASISTRATUS permission to dissect criminals condemned to death, and a great number were used in that way, but so far as history informs us, no subsequent ruler ever gave permission of this sort, and through all the centuries down to the present time, animals have been used to increase the stock of human knowledge by every principal investigator in the field of anatomy and physiology. Now, by reason of increased knowledge brought by animal experimentation, serum and toxin therapeutics, we in this generation have gone a step further and have discovered means of arrest and cure of some of the worst scourges known to mankind. Shall the cranks prevail and by creating false sentiment succeed in preventing the further development of bacteriology? We trust not brethren, but *let us beat Senate bill No. 1063!*

NOSTRUMS AND PHARMACISTS.

The report of a committee on a prize for an essay on price-cutting by druggists (signed by the dean of the Chicago College of Pharmacy, by a member of the American Pharmaceutical Association, by a wholesale jobber in drugs who largely advertises abortifacient nostrums, and by the "promoter" of a proprietary "tonic" advertised only in the daily press), announces that the highest achievement of the pharmacal skill of the close of the nineteenth century, is the nostrum, and eulogizes this "grand result" of "scientific" acumen in the fulsome style so characteristic of the "promoters" of dubious enterprises. This fulsome eulogy which seriously reflects on hundreds of reputable pharmacists is as unjust to them as it is historically false. Crabbe, nearly a century ago, sang ancient patent medicines in "The Borough":

> With monstrous promise they delude the mind
> And thrive on all that tortures human kind;
> Void of all honor, avaricious rash,
> The daring tribe compound their boasted trash;
> Tincture or syrup, lotion, drop or pill,
> All tempt the sick to trust the lying bill,
> And twenty names of cobblers turned to squires,
> Aid the bold language of these blushless liars,
> How strange to add, in this nefarious trade,
> That men of parts are dupes by dunces made;
> That creatures, nature meant to clean the streets
> Have purchased lands and mansions, parks and seats;
> No class escapes them, from the poor man's pay
> The nostrum takes no trifling part away.

The patent medicine traffic herein commemorated had, however, begun more than half a century previously. In 1711 in New Jersey a Mrs. McMaster sold "Tuscarora Rice a Cure for Consumption." Concerning the eighteenth century patent medicine trade in other English-speaking countries Mr. Alpe states (*Pharm. Journal* and Transactions, 1887), that the *Gentleman's Magazine* for 1748, contained a "Pharmacopeia Empirica," which shows that patent medicines were exceedingly numerous in England in the eighteenth century. The "Pharmacopeia Empirica" was compiled that "persons who could not afford the expense or might not care to be governed by the advice of the physician and apothecary, might know where to apply on occasion for an appropriate remedy." It contained 202 patent medicines, 90 per cent. of which were manufactured in London. This list, therefore, was far from complete. Patent medicines for gleet, gonorrhea, syphilis, impotence and sterility are exceedingly numerous. One man advertises "belts" for cure of "leprosy," at $1.50 each. "Necklaces" for "cutting teeth" are advertised $1.25. "Girdles" for the "itch" are advertised at exorbitant prices. Among the patent medicines mentioned are "James's fever powders" at $1 per "paper;" "Godfrey's cordial" at 75 cents a bottle; "Daffy's elixir" at 63 cents; "Bateman's drops" at 25 cents; "Stoughton's bitters," and "Betton's British oil." The highest priced articles are "Dr. Bellost's pills" for rheumatism, at $5.00 per box, and "Profely's pills" for syphilis at $2.50.

Mr. Alpe gives a list of patents for medicines, beginning with one in 1711 by Timothy Byfield, described as "A new and most vsefull chemicall preparation and medicine publickly known" by the name of his "sal oleosum volatile which, by abundant experience, hath been found very helpful and beneficial as well in uses medicinall as others and will very much tend to the public use and benefit of our subjects." Robert Stoughton patented his "elixir magnum stomachi" in 1712 (now surviving as a bar room bitters). The next patent was in 1722, obtained by Robert Eaton for a "styptic" medicine. Benjamin Okell came next (1726) with "Dr. Bateman's pectoral drops." "Betton's British oil" was patented in 1742; "Hooper's female pills" in 1743; and "James's fever powder" in 1744. About this date the patenting of medicinal compounds became more common—three or four in a year.

Some of these display polypharmaceutic tendencies. Thomas Greenough got a patent in 1744 for a toothache tincture containing twenty-six ingredients. Nathaniel Godbold obtained one in 1785 for a vegetable balsam, into which he had worked fifty-two ingredients. In 1805 Richard Brandreth the elder was given a patent for some constitutional pills with ninety-one ingredients. Mr. Godbold patented his balsam in 1785, and "improved" upon it in 1798. "John Ching's worm lozengers" were patented in 1796, and "improved" in 1808 by Rebecca Ching. The object of the "improvement" was to evade the time limitations of the patent laws. Some modern medicinal preparations seemingly originated in these patents which, however, were often prescriptions of physicians stolen, "improved" and patented. "Friar's balsam," according to Mr. Alpe, originated as a patent obtained in 1777, by Robert Grubb, for a certain medicine called the "Friar's drop for cure of venereal disease, scurvy, rheumatism, strangury and gleet, without any electuary or pills, in every stage of the complaint, or without any confinement or particular regimen." To make the "drops" rectified spirits are added to calomel, purging anatomy, guiacum wood, balsam Peru, extracts of hemlock, sugar candy, oil sassafras, tartaric acid, and gum Arabic.

Patent nostrums are fetich survivals of polypharmacy of the medicine men. Their atavistic persistence in the nineteenth century is a reflection alike on popular intelligence and commercial honesty. The signature of the dean of a pharmacy college to such a fulsome endorsement as that described can not but be regarded as evidence of unfitness for the position of teacher. The American Medical Association, by creation of its Section of Pharmacy, has endeavored to elevate the status of the pharmacist. Performances like these render the performers (if a member of the American Pharmaceutical Association) *persona non grata* as a delegate to the Section on Materia Medica and Pharmacy of the American Medical Association.

HIS ROYAL HIGHNESS, THE PRINCE OF WALES, F.R.C.P.

The London *Lancet*, of July 24, devotes an editorial to an explanation of the significance, as it understands it, of the recent conferring of an honorary fellowship of the Royal College of Physicians on the Prince of Wales. Judging from the tone of this leading editorial, for we have no other source of information, the appointment has been looked upon somewhat askance by certain members of the medical profession in Great Britain. The ordinary significance of an honorary degree is, that its recipient possesses eminently respectable, if not pre-eminent qualifications in the particular branch of learning represented by the degree, and to make such a bestowal upon one who has notoriously had no special training, solely on account of his official position, has upon its face a certain stamp of grotesque impropriety. The *Lancet* admits that the granting of an honorary medical title, no matter who is the recipient, will seem ridiculous to some, if he has had no medical training and can claim no medical knowledge, and in this country there is no doubt that such a proceeding would meet with general ridicule; and the learned body or corporation granting such a distinction would suffer more or less severely in public estimation. One can not here speak as an expert on the special impropriety of the action of making the heir to the British throne an honorary member of our profession, but it is evident, from the semi-apologetic character of the *Lancet's* leader, that something of the sort was more or less appreciated by our transatlantic brethren, and hinted if not freely and openly discussed. Some members of our profession evidently questioned whether it was materially elevated by making official position, even the highest, a qualification for its honors, and in a strictly medical and scientific point of view their doubts are amply justified. Our contemporary, however, probably states the more general and popular opinion of our British *confrères* when it says that, as representative of her Majesty the Queen, it is perfectly appropriate and germane to his position that he should enjoy high official status in all national institutions, including the higher professional corporations, and that his gracious action in the acceptance of the compliment (it does not venture to call it an honor) is, in its opinion, "a pleasing recognition of the whole profession of medicine."

In the light of the *Lancet's* editorial, and considering the peculiarities of British political and social institutions, we must admit that there is much force in its way of stating the case, and that the ridiculous aspect that is at first sight most obvious is very materially softened down. It would not take well in this country to have an honorary M.D. bestowed on President McKinley or Vice-president Hobart on the sole ground of their official rank, and neither they nor the profession would feel that honor had been bestowed or received; but circumstances are not the same in Great Britain, where so much depends on recognition by royalty and the aristocracy. One has only to glance at the rosters of English medical and charitable institutions to see how important such recognition and patronage is regarded. If this "pleasing recognition" of the medical profession will in any way or to any degree elevate or improve its social status in Great Britain, we in this country can only express our satisfaction with such a result. It is not so very long since this Journal had occasion to notice what appeared to be a lack of due recognition of the medical profession by the highest social arbiters in Great Britain, and again to notice some British exceptions to its criticisms. If we could take this acceptance of a medical honor by the Prince of Wales as in any way, directly or indirectly, intended as an answer to such criticism, the critics may congratulate themselves upon having had some influence in producing what the Journal trusts will be a benefit to our English *confrères*. The Journal would also congratulate H. R. H. the Prince of Wales on having been made an honorary member of the profession which above all other secular ones has cherished and maintained a high standard of honor and ethics, and which is second to none in its honorable history and traditions. Of all the various honors he has received he need not consider this among the least, even with full recognition of the fact that its conferment is solely due to the special conditions existing in a country where honors are hereditary and simple manhood or scientific merit are secondary matters as regards social consideration and standing.

KOCH'S EXPERIMENTS WITH THE RINDERPEST.

The recent issue of the first official reports of Koch's investigation of the rinderpest in South Africa is attracting much attention to this subject from the African and Indian bacteriologists and veterinarians; and there is strong reason to believe that his experiments in connection with the immunization of cattle from this deadly plague will result in the saving of millions of animals. The real import of Koch's work can only be understood when we consider that a low estimate of the annual monetary loss from cattle destruction alone, by this disease, is over thirty million dollars. There is an extra significance in the fact that this loss is sustained by a people generally poor in other than agricultural ownings.

The details of Koch's actual system of practical procedure are of such interest as to command the attention of every one interested in the development of the serum treatment of disease, and the following epitome is offered to our readers.

On Koch's arrival in South Africa in December, 1896, he found a belief among the Free State farmers that the bile of an animal dead from rinderpest, mixed with blood or other liquid, would cure the disease. Experiments with bile as a curative agent were negative. Koch then directed his attention to the inoculation of cattle with cultures of the alleged specific microörganisms of rinderpest. Such inoculations did not produce any symptoms of the pest, and offered no protection. Having failed in confirming any of the so-called discoveries of the origin of rinderpest, experimentation was directed to the main object of the visit to discover a process of attenuation of the virus of rinderpest, so as to use it by inoculation as a certain preventive measure.

Koch found that a mitigated rinderpest could be produced in sheep and goats, animals ordinarily less susceptible to the disease than cattle. Inoculations were continued to the seventh generation, and the later serums produced mild manifestations of the disease. In the hope that by passing the disease through the smaller animals it might be given to cattle in a mild but protective form, Koch inoculated four heads of cattle with the virus of two sheep and two goats, after it had passed five times through the latter animals. The two cattle inoculated with the sheep virus exhibited a violent and fatal form of rinderpest, giving the inference that passage through the sheep intensified rather than lessened the strength of the virus. The results of the inoculations with the goat virus were more encouraging and further experiments were made with the goat virus exclusively, showing very slow, but actual attenuation of the infection by passage several times through the animal. None of the goats died, but one typically infected animal was killed, and lesions similar to those seen in cattle dying at the same stage of the disease were noticed. In this connection Koch says: "These experiments explain satisfactorily the widely different statements concerning rinderpest in eep and goats. Many farmers are of opinion, and this I have seen myself on rinderpest farms in the Free State, that these animals may graze with diseased cattle without contracting rinderpest, while, on the other hand, some have reported that the pest had appeared in their flock of sheep and goats, and carried them off in large numbers, after it had already disappeared among the large stock. My opinion on this subject is that sheep and goats at first contract rinderpest in such a mild form that it can not be diagnosed, and that the pest gradually becomes more virulent through being continuously propagated within these animals' systems. Then the symptoms became naturally more distinct, and in some cases the disease may even take a fatal course."

No other animals than those mentioned were found susceptible to the disease, and birds were particularly exempt from the action of the rinderpest virus.

Chemic attenuation of the virus was unsuccessful; even glycerin, which preserves almost all similar infective materials, destroyed the potency of the virus. Salt solution and distilled water failed to give any protection or immunity. Dessication for a period of four days, rendered the virus innocuous, and failed in protective action.

The most important and the really practical experiments were those relating to the animals recovered from rinderpest, commonly called "salted" cattle. Inoculations with rinderpest blood failed to produce symptoms in the "salted" animals, while the "unsalted" cattle promptly died of genuine rinderpest. The serum of the blood of "salted" cattle was then injected into the susceptible animals. At first, 100 c.c. of serum were used, and on the following day 1.5 c.c. of rinderpest blood was hypodermically injected, without significant symptoms, and on the sixth day there was a reinoculation with negative results. Another animal was inoculated with a mixture of blood and serum without injury. Thus it was difinitely established that the serum of the immune or "salted" cattle possessed a certain protective power, and it is from this fact that the important results will be eventually obtained.

The protective power of the serum from the immune animals is not very great, and probably only lasts a short time, and the quantity of serum necessary for general immunization is too great to render the inoculation on a large scale practicable. However, animals have been immunized to such an extent by a mixture of serum and virulent rinderpest blood as to withstand an injection of 20 c.c. of rinderpest blood, a ten-thousandth part of which is the ordinary fatal dose. Such immunity Koch judges to be equal to that of the "salted" cattle. Koch also discovered that the bile of cattle dead from rinderpest, injected under the skin in 10 c.c. doses, is sufficient to render healthy cattle immune by the tenth day at the latest. Four weeks afterward an injection of 40 c.c. of rinderpest blood caused no injurious results.

In concluding his report Koch says: "Both these above-mentioned facts convince me that rinderpest can be eradicated with but little difficulty, and within a comparatively short time, by putting these methods into practice. The method of immunizing cattle with serum may be used in order to separate from infected areas those tracts of country which are still free from the scourge by means of forming a broad belt between them in which all the cattle are inoculated with the vaccine. The protective properties of the bile will be of inestimable service in infected parts. Nearly every case of rinderpest supplies a greater or lesser quantity of vaccine for those animals which are still healthy."

THE ADRENAL TUMORS GROWING OUT OF THE KIDNEY.

The study of the ductless glands seems to be just making its beginning. The thyroid presents an interesting example, but as yet our knowledge of this organ remains almost as unsatisfactory as complete ignorance. The absence of the thyroid determines a pathologic condition known as myxedema, its abnormal activity another condition known as exophthalmic goiter. The former disease has been successfully treated by the implantation of pieces of living thyroid or by feeding fresh or dried thyroid tissue, and the latter has in some cases been cured by the removal of the enlarged or vicious thyroid gland.

An analogous condition prevails in the case of the adrenal glands. When these glands are destroyed by tuberculosis, or by other diseases, a condition known as ADDISON'S disease is instituted. This disease is characterized by a bronzing of the skin, a loss of strength and a rapid, small soft pulse. All the other symptoms of a wasting disease come on and life ends in asthenia. There is however, a condition of great hypertrophy or hyperplasia of the adrenal tissue which shows itself in various degrees of toxicity. In the exaggerated form the patient has a slow pulse of remarkably high tension, a very light colored skin and many of the external appearances of renal sclerosis. These patients however pass normal urine and sometimes die of apoplexy even though quite young. The autopsy reveals adenoid tumor of the kidney resembling the adrenal tissue with or without similar metastatic tumors in the lungs or bones. The lipomas of the kidney so often reported in the literature are, many of them at least, of adrenal origin.

There has been no proper exposition. in our medical literature, of the phenomena of adrenal tumors in the kidney. GRAWITZ first pointed out the origin of these neoplasms (*Langenbeck's Arch.*, vol. 30), and many contributions have been made to the pathologic study by the aid of the physiologic researches of CYBULSKI and SZYMONOWICZ. (*Gazette lekarska*, 1895, XV, and *Pfluger's Archiv*, 1896, LXIV.) These investigators found that the removal of both adrenals produced the small rapid pulse of ADDISON'S disease, and that the injection of the adrenal extract produced a slow pulse of high tension. The injection of the venous blood from the adrenals of one animal into the veins of another, produced the same effect as the adrenal extract. OLIVER and SCHÄFER confirm these observations. Any one may confirm them, in a measure, by using the adrenal extract for its digitalis-like effect.

To the diagnostician and surgeon these phenomena are of the greatest interest. There came under the writer's observation some years ago, a man complaining of his inability to give up the morphin habit. He began to use the drug for pain in the back and severe headaches, which were accompanied by violent palpitation of the heart. After long confinement in a hospital with a gradual diminution of the morphin and the substitution of small doses of atropin combined with careful diet and regular bathing, his health improved, but the pain in his back remained. His headaches were almost constant and only partially controlled by atropin. An examination of his back now disclosed the presence of a tumor just under the last rib and apparently in connection with the kidney. With the patient's consent this kidney was explored through a lumbar incision and found to be attached to the palpable tumor. It was accordingly removed. The man recovered from his pain and headaches and the tumor was found to be an adrenal parathelioma growing out of the middle of the kidney. In another case long taken to be renal sclerosis, the patient was suddenly attacked with symptoms of pneumonia without fever. This was followed by a pleuritic effusion of a bloody color and later by death. The pulse was all the time of the highest tension although the skin was pale. At the autopsy a large adrenal tumor of the kidney was found with multiple metastatic tumors in the right lung.

The size of the tumor does not always determine the virulency of the intoxication. In some cases a small tumor results in such a virulent product that the young sufferer dies of cerebral hemorrhage, while in other cases the tumor reaches a prodigious size without any marked circulatory symptoms.

It is at least remarkable that the increase in the thyroid produces an intoxication, often fatal, with symptoms almost the opposite to those produced by an analogous increase in the adrenals, and that the destruction of the thyroid is accompanied by a remarkable condition (myxedema), the most pronounced symptom of which is related to the skin, while the destruction of the adrenals results in a very different condition (ADDISON'S disease), the most manifest symptom of which is also found in the skin.

These analogies are certainly suggestive, even to the therapeutist, and ought to lead to some rational use of the much abused glandular extracts.

THE SECTION ON PRACTICE.

If nothing had been produced at the Semi-Centennial outside of the papers of this Section, the meeting would still have been of immense value to the American Medical profession. The current number of the JOURNAL containing the important discussion and committee report on serum diagnosis is one that no practitioner can afford to be without, and Dr. MUSSER and his colleagues have set a model that will be very difficult to surpass.

These papers, however, valuable as they are, should serve the additional purpose of further stimulating effort, and realizing to the full extent the wise purpose of the founders. There is much room for original experimentation and it is a matter of congratulation that the subject of prize essays has again been revived with so bright a prospect of ultimate success.

The JOURNAL, as it is now produced, covers each year nearly the whole field of medicine, as the Sections now number twelve.

The already great but growing membership brings that material power which will insure success. Let the whole prof [illegible] in [illegible]ATION the determination to show the world what the American medical profession can do for science and humanity when united in collective effort.

BRITISH MEDICAL ASSOCIATION—SPECIAL RATES.

The Grand Trunk Railway System will sell reduced rate tickets to all physicians attending the British Medical Association meeting at Montreal, August 31 to September 5. Tickets will be sold August 28, 29 and 30, good returning three days after adjournment of the convention, at rate of one and a third fare for the round trip. Through Pullman palace vestibuled sleepers daily between Chicago and Montreal. For tickets and sleeping car accommodations apply to L. R. MORROW, G. P. & T. A., 103 Clark St., Chicago.

CORRESPONDENCE.

Treatment of Typhoid Fever.—An Answer.

DAVIS, W. VA., Aug. 3, 1897.

To the Editor:—In the JOURNAL of July 10 I notice an article on the "Treatment of Typhoid Fever," by Dr. Upshur of Richmond, Va., and his criticism of Dr. Woodbridge. His treatment especially attracted my attention. He says: "Dr. W. makes claims of such brilliant results that one is startled, and the question arises, have I been groping and blundering all these years?" In the outset he desires it understood that he has never used it, not because of any *spirit of prejudice or unfairness*, but because upon *careful* consideration the brilliant results *claimed*, to *his* mind, disproved the facts, and he did not feel willing to trifle with the lives of his patients by uncertain experiments. He has never tried it. How can we know of anything unless we try it? How does the Doctor do when he hears of a new drug, for instance, antitoxin in the treatment of diphtheria? Did he use it after reading what it did at the hands of others? Does he not use vaccine virus that was hooted at by many for years? Many wise and learned physicians laughed at it and cried it down, but what physician does not now use it, believing firmly in it? It was an experiment at first, but after it was perfected, tried and proven, it became a *fact*. How can he judge of a treatment (no matter what) if he does not give it a trial—a fair trial? Does he practice medicine and never try what others recommend? Does all his practice consist of what he knows most positively are *sure cures?* Can not others teach him? Have we to depend on foreign physicians entirely? Have we not just as wise, just as learned men in our own country as they have across the water? Is it not just as possible for the Woodbridge treatment to succeed as for antitoxin?

I have used Woodbridge treatment exclusively for two years, without the loss of a single case. If I should have typhoid fever I should feel safe, if I took it or had a physician give it who understood just how to use it. I lost from two to five cases every year before I used it. Does Dr. Upshur think the ability to diagnose typhoid fever is confined to himself and a certain few others? He says, "there *must* have been a mistake in diagnosis." I used for years iodin and carbolic acid and cold baths, and had good nurses. I had a case last year who had four hemorrhages from the bowels, temperature ranging from 104.5 to 105.5 degrees, and she got well in three weeks. I used the Woodbridge antiseptic tablets. Her husband was sick with the same disease this summer, between nine and ten weeks, and is really not well yet. He was on the old treatment and under a physician who does not believe in Woodbridge. Since I have been using the Woodbridge antiseptic tablets I have not had a case sick over four weeks, and they rarely run more than three before being discharged. Only the one mentioned had hemorrhage from the bowels and four or five deliriums, which soon passed off. Several cases came to my office with temperature 105 to 105.5 degrees when I first saw them. Do I make mistakes sometimes in diagnosis? Yes, and so do all of us; Dr. Upshur included.

When I see physicians all around me using the old treatment and working and fighting with might and main with this dread disease, I am all the more ready to sound Dr. Woodbridge's praises for his wonderful discovery, and add my voice to the many in urging all physicians to try it and prove its efficacy. I saw one of our physicians lose four cases in one family on the old treatment. The Doctor was discharged and another one called in, who, although he did not use the formula of Woodbridge, used a part of it—thymol, guaiacol carbonate and hydr. chlor. mite, and brought the rest of them through.

Dr. Upshur seems to think that Dr. Woodbridge breaks a law of ethics. I can not see how he does, for if Dr. Upshur would recall how often he puts the make of drug he wants on his prescriptions, he would see in some measure while that is a sort of advertisment for the firm, his motive is to secure what he considers the best make for his patient. I often do this myself, for I have carefully watched and know whose preparations act best for me. Dr. Upshur speaks of the years of experience of the great men past and present, of the convincing truth of their writings, etc. It is true in most instances, but can not others come forward thinking and studying and find out new things and improve on what has already been found out and teach you and me? To sum up: What is our object in this great science of medicine? Is it not to relieve suffering, to cure disease, to get our sick ones strong again, and the sooner the better? I for one intend to read, to study, and to work, but use good common sense with it, and do my very best for my patients. I am heart and soul with Dr. Woodbridge, and firmly believe he has made a great discovery and advise all my brother physicians, who have not already studied and tried it, to do so. Watch it carefully and you can not fail to have your efforts crowned with success. Anyway, do not condemn before giving it a fair trial.

Fraternally, B. M. SMITH, M.D.

Criticism of a Critic.

CLYDE, N. Y., July 28, 1897.

To the Editor:—In the number for July 24, page 196, I notice under the title "The Jubilee Meeting," that among your exchanges there is one journal, *Buffalo Medical and Surgical*, which is deeply grieved that the representative of the anarchistic element of the profession of this State—"president of the Medical Society of the State of New York," was *not* allowed to participate in the proceedings," etc.

The writer also laments that "a great medical society" was thus ignored.

If the writer was not in his swaddling clothes at the time, does he fail to remember the insurrection in which he and his fellow-revolutionists were engaged—an insurrection the purpose of which those revolutionists boldly proclaimed was the expunging of the Code of Ethics from the Constitution of that "great medical society" by which, since 1807, it had been governed?

This mournful state of feeling, mingled with much pity, is so intense that he sorrows because Dr. Davis was not magnanimous enough to allow it, so long as it "would not have diminished the renown that is so justly accorded to the *Father of* the ASSOCIATION." Herein lies a great mistake of the writer. If he well knew of what he was writing, he knew that Dr. Davis had always protected the Code of Ethics from any and all invasions, and he ought to have known that had the representative of a "new code" been allowed, by vote, "to participate in the proceedings," it would *not* "have been a graceful act." On the contrary, it would have been a *disgraceful* one.

If the revolutionists before referred to desire to "participate in the proceedings" of future meetings of the AMERICAN MEDICAL ASSOCIATION, let them "confess their manifold" errors of the past, come to the *front* door, and they will "receive the right hand of fellowship."

D. COLVIN, M.D.

Carbohydrates in Diabetes.

PARIS, ILL.

To the Editor:—I think Dr. E. L. Munson is right in allowing a moderate amount of carbohydrates in diabetes mellitus. I have done so for the last eight years, and the results have been better than under a strict proteid diet.

I also allow the patient to drink all the water he wants, because it dilutes the urine and makes it less irritable to kidneys and bladder and, I think, lessens the danger of coma.

Respectfully, W. H. TEN BROECK, M.D.

PUBLIC HEALTH.

A Yellow Fever Ship at Cape Charles.—July 30 advices of the arrival of the Norwegian bark *Nor*, with a suspected case of yellow fever have been given out. Two cases developed on the vessel at Kingston, Jamaica. The bark was accordingly sent to the quarantine at Fisherman's Island.

Infectious Disease Hospitals of Massachusetts.—Legislation that will place restrictions upon the building or establishment of homes for consumptives and the like, in towns and cities is sought in that State. The unanimous approval of the boards of aldermen and health, plus that of the mayor, will be prerequisite for a license for all private sanitaria for contagious diseases. What contagious affections are, is thus defined: "The following diseases are infectious and contagious diseases, and diseases dangerous to the public health within the meaning of this act: smallpox, diphtheria, phthisis or pulmonary tuberculosis, membranous croup, measles, scarlet fever, typhoid fever, yellow fever and cholera." The proposed act provides that "no infectious or contagious disease, or other diseases dangerous to the public health, shall be treated or cared for in any city or town, in any hospital, home, or other like institution, not a public hospital maintained at the expense of said city or town, or of the commonwealth, or receiving endowment or assistance therefrom; provided, however, that the board of aldermen of any city, by unanimous vote, with the approval of the mayor and board of health thereof, and the board of selectmen of any town, by unanimous vote, with the approval of the board of health thereof, may license any private hospital, home, or any other like institution, of said city, to treat and care for any of said infectious and contagious diseases, or other diseases dangerous to the public health."

State Supervision of Medical Practice in Rhode Island.—The following are some of the principal regulations governing the issuance of certificates to practice medicine in that State, as adopted by the Board of Health of the State: All applicants applying for a certificate to practice medicine in the State of Rhode Island, presenting a diploma from any foreign medical school must pass an examination before the State Board of Health upon the following subjects: Anatomy, physiology, chemistry, therapeutics, materia medica, surgery, theory and practice of medicine, obstetrics, gynecology, hygiene and State medicine. An average grade of 80 per cent. will be required as conditions of receiving a certificate to practice medicine or surgery in this State. Diplomas from all recognized medical colleges in the United States requiring a minimum of three years study of medicine and two courses of lectures for graduation, prior to 1885, shall be recognized as in good standing, and diplomas issued by the same prior to that date, properly verified, shall entitle the holder thereof to a certificate to practice medicine and surgery in this State. For the ten years ending Jan. 1, 1895, all medical colleges exacting the foregoing requirements, shall, by virtue of such fact, be recognized as in good standing and to include the year 1891, but no medical college shall be recognized as in good standing which has not, since 1891, possessed the foregoing requirements, and which has not, in addition, exacted an entrance qualification and attendance on three regular courses of lectures, no two courses to have been given in any one year, as a condition of graduation. On and after July 1, 1895, no medical college shall be recognized as in good standing which does not require the entrance qualification representing as a minimum a high school diploma, or its equivalent, as a prerequisite for matriculation; which does not possess an adequate equipment for teaching medicine; which has not the clinic and hospital facilities, based upon a minimum municipal population of fifty thousand, and which does not have an active faculty embracing the departments of anatomy, physiology, chemistry, therapeutics, materia medica, surgery, medicine, obstetrics, histology, pathology, bacteriology, ophthalmology, otology, gynecology, laryngology, hygiene and State medicine, and which does not enjoin attendance upon 80 per cent. of four regular courses of instruction, of not less than twenty-six weeks each, in four different years, and which does not exact an average grade of 75 per cent. on examination, as conditions of graduation. A medical college shall be recognized as in good standing, in which the student is conditioned in one or more of the branches as requirements for matriculation, or that admits to advanced standing, students that are matriculants of colleges of pharmacy, or colleges of veterinary medicine, or upon the possession of an academic degree.

Meeting of the State Board of Health of Michigan.—The State Board of Health held its summer meeting in Sand Beach July 30 and 31, 1897, for the purpose of examining plans for State institutions and the transaction of other business. Plans and specifications were examined and recommendations made for a hospital cottage for female patients at Michigan Asylum, Kalamazoo. Plans and specifications were examined and recommendations made for a hospital building and also for a work shop at the State School for the Deaf at Flint.

President Wells congratulated the Board on the fact that at the recent session of the legislature a small appropriation was made which enables the Board to fulfil the Act of 1895 relative to teaching in the schools how to restrict the most dangerous communicable diseases; he suggested that the United States life saving station at this place may be examined by the members of the Board and mentioned in this connection the work of the Board relative to the resuscitation of the drowned. The plan recommended by the Michigan Board necessitates the action of only one person, whereas other methods necessitate action by two. At this meeting Secretary Baker presented a paper on the treatment of the drowned, suffocated and electrically shocked, to be published in the annual report. The Board's leaflet on the treatment of the drowned was slightly amended, a new edition ordered printed and copies to be distributed to life saving stations, lake summer resorts and other places around the State. The leaflet includes rules for efforts at resuscitating persons electrically shocked.

Dr. Belknap brought up the request of a local health officer that the State Board supply blanks for the use of householders and physicians in reporting contagious diseases. Secretary Baker pointed out the fact that the appropriation was not sufficient to enable the State Board to print so many blanks as would be required for that purpose; under such circumstances he claimed it was the duty of the various local boards of health to supply those blanks.

Professor Fall brought up the subject of the collection of samples of water from different parts of the State to be tested for chlorin in order to map out the normal amount of chlorin in the natural waters about the State to enable analysts to judge of the safety of samples of water hereafter examined, with a view to their use as water supplies. Professor Davis of Alma College, who is working on the State geological survey, is to collect samples of water in the eastern part of the State and send them to Professor Fall for examination. Professor Fall's map relative to chlorin in natural waters relates thus far mainly to the southern part of the State. He is now preparing to have samples of water sent by mail, more cheaply than heretofore by express.

The subject of quarter-centennial celebration of the establishment of the Michigan State Board of Health, in Detroit, July 30, 1898, was considered. Special subjects were referred to the several members of the Board who were charged with the duty of preparing for presentation at that meeting papers on a number of important subjects. The Secretary was directed to issue to the several ex-presidents and ex-members of the Board formal invitations to be present and take part in the quarter centennial celebration. The President and Secretary of the Board were appointed a committee to attend the meeting of the National Conference of State Boards of Health in Nashville, Tenn., Aug. 18 and 19, 1897. The two delegates were authorized to vote at that meeting for the proposed amendment of the rules for the transportation of corpses, the design being to have such rules uniform throughout the United States and adjoining provinces.

Dr. Cattermole of the office of the Board, was asked to give special study to the subject of the best measures for local health officers to take in connection with the State Laboratory of Hygiene, for the bacteriologic diagnosis of the dangerous communicable diseases.

The subject of the alleged pollution of the St. Clair River was brought up by a letter from a health officer of a township situated on that river, who claimed that there is "a large and increasing amount of sewage in the waters of the river St. Clair, produced by the discharge of the sewers of Port Huron and St. Clair cities into said river above this point." He suggests "that such oversight be used by the State Board of Health, as would prevent an accumulation of sewage matter in all the rivers of this State to such an extent as shall be dangerous to the public health." Secretary Baker mentioned a paper read at the last meeting of the Michigan Society of Engineers, by Engineer Williams of the Detroit Water Board Office, pointing out the facts relative to the unusual occurrence of typhoid fever in Detroit immediately following the dredging of sewage sludge from the bottom of Black River, Port Huron, and the emptying of that sludge into the St. Clair River. Secretary Baker read a communication from the Secretary of the Massachusetts State Board of Health, in reply to his letter of inquiry, which says: "In regard to the general act in force in this State for the protection of the purity of inland waters, I can say without hesitation, that the Act as amended in 1888 is one of the most important and valuable laws ever enacted in this State. It has already accomplished a great deal for the purification of public water supplies and the adoption of efficient methods of sewage disposal in cities and towns, and has undoubtedly saved to the State a far greater amount, financially, than has ever been appropriated for the purpose of the Act. Many towns and cities would, undoubtedly, have adopted unwise and expensive schemes had it not been for the enactment of this law." "The law was amended in 1888 . . . and appears to be at present as perfect a law as can be asked for." The subjects of sewage filtration laws and the protection of the purity of the inland waters of the State, was referred to the two Committees of the Board on Water-supply and Sewerage, Professor Fall to act as chairman of the joint committee.

A letter from Samuel G. Milner, M.D., member of the Board, not present at this meeting, proposed several subjects for action, including the prevention of infection through milk supplies, the inspection of sewage and other sanitary arrangements at Michigan health resorts, the isolation of tuberculous inmates in asylums and poorhouses, all of which subjects seemed to call for further legislation, and were therefore referred to Judge McAlvay, the committee on legislation.

Professor Fall reported the result of his work in the preparation of a pamphlet for the use of teachers in complying with the law which requires the teaching in the public schools of the best measures for the prevention of the most important diseases. Several hours were devoted to the examination of the work, and in the discussion of the subject. The Secretary was directed to have copies made, and one sent to each member of the Board for further study, with the view of perfecting it for publication.

A vote of thanks was extended to Mr. Wells for his entertainment of the members of the Board during this meeting and for the courtesies extended to them during their stay in Sand Beach.

BOOK NOTICES.

The American Text-book of Operative Dentistry. In contributions by eminent American authorities. Edited by Edward C. Kirk, D.D.S., Professor of Clinical Dentistry, University of Pennsylvania, Department of Dentistry. In one very handsome octavo volume of 699 pages, with 751 engravings. Cloth, $5.50; leather, $6.50, net. Philadelphia and New York: Lea Brothers & Co.

The contributors to this volume are R. R. Andrews, Henry H. Burchard, Calvin S. Case, William E. Christensen, Dwight M. Clapp, M. H. Cryer, Edwin T. Darby, C. L. Goddard, S. H. Guilford, Louis Jack, Edward C. Kirk, Louis Ottofy, C. N. Peirce, J. D. Thomas, Alton Howard Thomas.

This book is a successful attempt to bring modern pathology to bear upon the old traditions and has resulted in an essentially modern book, retaining the essence of the past literature which was of value, so arranged and presented as to meet the requirements of those for whom it was written. From a literary standpoint the work is a distinct advance on the text-books of the past, and will add to the reputation of the dental profession in this line.

The surgical anatomy of the teeth and jaws is correctly given in every detail, and the subject of implantation of teeth receives careful attention. Dr. Younger is given the credit justly due him of the authorship of modern implantation. The chapter on malformation is especially good. In mechanical dentistry the work will be found fully up to date. As a whole, we have unstinted praise for this work.

Reference Book of Practical Therapeutics. By various authors, edited by Frank P. Foster, M.D., editor of the *New York Medical Journal.* Vol. 2, pp. 618. New York: D. Appleton and Company. 1897.

The following are the contributors to the volume: Samuel Treat Armstrong, M.D., Ph.D.; Samuel M. Brickner, M.D., William B. Coley, M.D.; Floyd M. Crandall, Jeremiah T. Eskridge, Matthias Ganckton Foster, A. G. Gerster, M.D., Henry A. Griffin, M.D., Charles Jewett, A.M., M.D., Howard Lilienthal, M.D., Russel H. Nevins, M.D., Austin O'Malley, M.D., George L. Peabody, M.D., Frederick Peterson, M.D., Samuel O. L. Potter, A.M., M.D., Charles Rice, M.D., Solomon Solis-Cohen, M.D., James T. Whittaker, M.D.

This volume which is fully equal to its predecessor is arranged alphabetically and will be found of highest value for reference especially in relation to newer remedies, mineral springs and mineral waters. The index is very full and adds much to the value of the work.

We congratulate the distinguished editor on the completion of the work, which for convenience and completeness is unexcelled.

Eye-strain in Health and Disease. With Special Reference to the Amelioration or Cure of Chronic Nervous Derangements without the aid of Drugs.—By Ambrose L. Ranney, A.M., M.D., author of "Lectures on Nervous Diseases." "The Applied Anatomy of the Nervous System," etc., etc.; late Professor of Nervous Diseases in the Medical Department of the University of Vermont and of the Anatomy of the Nervous System in the New York Post Graduate Medical School, etc. Illustrated with 38 wood-cuts. One volume, royal octavo, pages viii-321. Extra cloth, beveled edges, $2,00 net. The F. A. Davis & Co., publishers, 1914 and 1916 Cherry Street, Philadelphia; 117 W. Forty second Street, New York; 9 Lakeside Building, Chicago.

The author of this volume is an enthusiast in the eye treatment of chorea and epilepsy and backs up his opinion with the recital of cases apparently cured by the correction of the eye defects. It must be conceded in the present inaccurate state of the treatment of epilepsy that it is well in all cases for the practitioner to consider the relation of eye strain to the particular case under observation and there is no question but in many cases the correction of visual defects will be found of great advantage.

A System of Practical Medicine, by American Authors. Edited by Alfred Lee Loomis, M.D., LL.D., and William Gilman Thompson, M.D. Volume ii. Diseases of the Respiratory System, Diseases of the Circulatory System and the Mediastinum, Diseases of the Blood, Diseases of the Kidney, Diseases of the Bladder and Prostate Gland. Illustrated, pp. 941. New York and Philadelphia: Lea Brothers & Co. 1897.

We have no hesitancy in pronouncing this system one of the best that has lately appeared; one altogether creditable to American medicine. In its pathology it is modern, in its treatment conservative and in diagnosis accurate and exhaustive. The careful reader will find himself fully informed of the latest teachings of the time and consequently well equipped for his daily work. As a work of reference it will be found very satisfactory, and the practitioner will make no mistake who follows its teachings closely.

The only criticism we make in relation to the book is that the old system of dosage is unfortunately adhered to throughout the volume.

Twenty-ninth Annual Registration Report of Births, Marriages and Deaths in Michigan for 1895. Lansing, 1897.

The report presents in the introduction the new laws affecting vital statistics, treating in Part 1, "Vital Statistics and Population." Part 2 presents a general discussion of births, while Part 3 is limited to marriage statistics. The "Incidence of Deaths by Months, Age, Sex, Color, Nativity and Nationality of Decedents," and "Causes of Deaths" are considered in Part 4, and vital statistics of Michigan cities in Part 5. Each part is replete with practical talks covering varied phases of the subjects. There are also meteorologic tables and two diagrams, one showing the comparative mortality from certain diseases for a period of twenty-seven years, and one showing age incidence of mortality from certain diseases by decimal periods. The report is much reduced in size as compared with former reports, this being secured by excluding all tables not essential to correct interpretation of the report.

Eleventh Annual Report of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania for the year 1895.

The first forty-one pages are devoted to the secretary's report and the minutes, then follow reports of various committees, inspections, quarantine, disinfections, epidemics, conferences and conventions, etc. "Correspondence and Legal Opinions" are considered at length, as are also the Acts of 1895 bearing on the protection of life and health. A chart of the Susquehanna River, showing the fall in feet per mile, and other charts showing pollution of various water supplies accompany the report and are of much interest, while the maps furnished by the weather service are of more than usual excellence. Throughout the report are illustrations (in colors) of quarantine station, maps showing epidemic areas, plans for contagious disease hospitals, etc.

Transactions of the Vermont State Medical Society for 1895 and 1896. Cloth, 445 pages. Published by the Society, 1897.

Among other papers read in the 1895 session are noted the president's address, "Some Suggestions Concerning the Examination of Blood;" the vice-president's address, "Chronic Gastritis;" "Cholelithiasis," by E. H. Martin; "Intestinal Indigestion; its Dietetic and Rational Treatment," by W. H. Porter; "The Medical and Surgical Treatment of Appendicitis," by S. C. Gordon; "The Border Lands of Insanity," by S. E. Lawton; "The Radical Cure of Inguinal Hernia," by J. B. Wheeler; "The Prostate, etc.," by L. B. Bangs; Diabetes Mellitus," by F. C. Morgan; "Blood Stains," by J. N. Jenne; "Antitoxin Treatment of Diphtheria," by E. R. Campbell, and "Cases of Tuberculosis Treated with Tuberculin and Antiphthisin," by L. M. Greene. The papers for the meeting of 1896 include: "The Cure of Hernia," by H. O. Marcy; "Acute Peritonitis, etc.," by W. H. Vincent; "Inebriety and Its Treatment," by W. S. Nay; "Diseases of the Rectum," by D. C. Hawley; "Puerperal Fever," by J. M. Hamilton; "The Operation of Shortening the Round Ligaments, its Indication and Technique," by E. H. Ross, and several papers on obstetric and other questions.

Eighteenth Annual Report of the State Board of Health of the State of Rhode Island for the year 1895, including the Report on Registration of Births, Marriages, etc., for 1894. Providence, 1897.

The report considers in detail sanitary improvements of towns, water supplies, meteorology, vital statistics, legislation for 1895, the wording of the medical law and examinations of diphtheria culture. There is also a record of all consumption cases in the State and a report on "An Epidemic of Typhoid Fever from Milk Supply." The appendix presents "Bacteriologic Results from Mechanical Filtration," "Drainage Areas," "Disposal of Sewage at Pawtucket," and "Experiments with the Howatson Filter," with illustrations of sewage plants, charts of water analyses and map of the drainage areas of the State.

Text-Book on Mental Diseases.—By Theo. H. Kellogg, A.M., M.D., late Medical Superintendent of Willard State Hospital, etc., etc. Octavo, 702 pages, illustrated by original sphygmographic tracings and photographs of the different types of mental disorder, pp. 776. Extra muslin, $6.00. New York: Wm. Woods & Co.

In our notice of this excellent work last week, through an oversight the line containing the name of Wm. Wood & Co., the publishers, was accidentally omitted.

Essays on Social Topics. By Lady Cook. Published by the Roxburghe Press, Westminster, London.

These essays consist of reprints from Woodhull and Claflin's *Weekly* and other essays on social topics and miscellaneous essays not before printed. As an iconoclast Lady Cook is an undoubted success and those interested in the history of all sides of the social question will be instructed by a perusal of these essays.

A Retrospect of Medicine. A half-yearly journal by James Braithwaite, M.D., London, assisted by E. T. Trevelyan, M.D., etc. London: Simpkin, Marshall, Hamilton, Kent & Co. July, 1897.

This volume of Braithwaite is fully equal to its predecessors and consists of carefully made abstracts from literature of the preceding six months. We note with pleasure that American medical literature is fairly represented.

Franklin and Marshall College Obituary Record. Vol. i, No. 1. Paper, 245 pages. Published by the Alumni Association, Lancaster, Pa., 1897. $1.

This publication is to appear annually and contain "a record of the lives of the deceased alumni of Marshall College and of Franklin and Marshall College." Vol. i, No. 1, contains the record of all deceased alumni from 1837 to June, 1897, the articles being grouped according to the year of graduation.

The Roller Bandage, with a Chapter on Surgical Dressing. By William Barton Hopkins, M.D., with illustrations; pp. 130. Fourth edition. Philadelphia: J. B. Lippincott & Co. 1897.

This well known book for the use of students and practitioners has been thoroughly revised and brought down to date. The illustrations are excellent.

NECROLOGY.

John N. Beach, M.D., West Jefferson, Ohio, who died July 17 (*vide* Journal, p. 252), was graduated in medicine from Starling Medical College, Columbus, in 1850. He afterward carried on further study in New York hospitals and colleges and in 1858 located at West Jefferson, practicing there until his death. After being commissioned surgeon of the Fortieth Regiment Ohio Volunteer Infantry in April, 1862, he was assigned to staff duty in September of that year. This service was continuous, as follows: [illegible] on of [illegible] Third Brigade, Army of the Kanawha, [illegible] of 1[illegible] [illegible] director of the Third Division (General Baird's), Army of the Ohio, in the spring of 1863 at Franklin, Tenn.; Surgeon of the First Brigade, First Division Reserve Corps, Army of the Cumberland, from July 24, 1863, until the re-organization of the army in October, after the battle of Chickamauga, and from that time until his muster out, he was surgeon of the Second Brigade, First Division, Fourth Army Corps. In the spring of 1864, in addition to his staff duties, he was assigned as operating surgeon in the hospital of the First Division, Fourth Army Corps, a position he held until the fall of Atlanta. He was mustered out at Nashville, Tenn., Dec. 6, 1864. He was professor of pathology in Columbus Medical College, 1875, surgeon general of Ohio from 1880 to 1885, and a member of the Madison County Medical Society, Central Ohio Medical Society, AMERICAN MEDICAL ASSOCIATION, and National Association of Railway Surgeons. He died at Chattanooga, Tenn., July 17, aged 69 years.

JOHN J. CURRAN, M.D., died from cardiac complications, after a month's illness, at his home in New York, July 24. He was a native of Newport, R. I., a graduate of the College of Physicians and surgeons, N. Y., 1888, associated in practice with his brother, Dr. Frank W. Curran, who survives, and a Fellow of the N. Y. County Medical Association.

EDGAR M. IKE, M.D., Jefferson Medical College 1888, of Altoona, Penn., died there July 29. He was born March 21, 1867.

A. B. CALHOUN, M.D., Newman, Ga., August 1, aged 89 years.——John W. Hocking, M.D., Govanstown, Md., July 26, aged 40 years.——Theodore B. McNabb, M.D., Fremont, Ind., August 7.——John W. Powell, M.D., Rush Medical College, Chicago, 1865, at his home in Peoria, Ill., August 8, aged 59 years.

MISCELLANY.

Personal.—Dr. Isaiah B. Sexton of Sparta, Kent County, Mich., is one of the thirty-three survivors of the 1812 war.

Large Bequests to Charities.—The will of Mrs. Nathaniel Thayer of Worcester, Mass., provides for some important institutions as follows: The Massachusetts General Hospital, $25,000; Eye and Ear Infirmary of Boston, $10,000; Lying-in Hospital and New England Hospital for Women, together, $20,000; Perkins' Institution, $10,000; Convalescent Hospital for Children at Wellesley, $5,000; Home for Incurables, $5,000, and also about $90,000 for humane and religious bodies, chiefly located in Boston.

Corrections in Membership List.—Received too late for publication in list of July 24:

Eaton, Frank B., San José, Cal.	1894
Gihon, A. L., New York, N. Y.	1876
Heffron, John L., Syracuse, N. Y	1897
Schnabel, E. D., Bethlehem, Pa	1897
Van Ettan, C. S., Rhinebeck, N. Y.	1895
Penny, Herbert T., Truro, Mass	1892

Post-operative Tetanus.—There are fifty-nine cases on record, and Cackovic adds another, described in the *Cbl. f. Chir.* of July 3, with a review of the literature on the subject. His case followed a lumbar nephrotomy, and he is inclined to think that the patient brought the germs with her into the hospital, as she came from a street which had just been deeply excavated for some purpose, and another patient with developed tetanus was brought soon after to the hospital from the same house. "They were probably in her organism, latent, and developed into virulence from the shock of the operation." The wound was drained with a rubber tube.

The Anatomy of the Novelist.—Our Gray is becoming pretty old, and the cover is getting loose. Some of the pages are torn and others are missing. We are in need of a new anatomy. This new anatomy should be in part original, and in part a compilation. The chapters that are compiled should be taken from the dissecting table. The chapters that are original should be taken from the works of the modern novelists of the romantic school. In a newly published novel that we recently picked up at a book-stall we came upon the following graphic description of the result of a duel between the hero and the villain: "The hero fell at the first shot. The surgeon bent over him. 'Safe,' he whispered. 'The bullet has grazed his temple, but had it gone an eighth of an inch deeper it would have severed the femoral artery.'"—*Medical Era.*

Longevity Among Centenarians, judging from newspaper items, is on the increase. Females now, despite their hardships, lead the company. Two widows, one in Croton, Vt., and the other in Lawrence, Mass., celebrated their one hundredth anniversary on July 31, while another in Lockport, N. Y., entered upon her hundredth year on August 4. Life Insurance authorities claim that only one in a million can attain so ripe an age. Beyond the fact of a long uneventful existence added to a certain imperturbability of temperment and simple regular habits there is not much need of inquiring into the real cause of longevity. "Wound up for a longer run" was the reported answer of a watchmaker, three years above the century mark.

The Prognostic Stage of Tuberculosis.—Dr. A. Mansfield Holmes of Denver, Colo., believes in the possible estimation of the recuperative power of tuberculosis. Out of 100 cases carefully studied by him he claims to have elaborated the law of disintegration as being the same in the leucocytes as in the system as a whole. He prepares the blood films, fixes, stains and mounts them. The finger of the patient antiseptically cleansed he pricks with a sterilized needle, uses the blood drop with due celerity and scrutinizes the shade communicated by the staining solution to the cell tissues. The leucocytes, he maintains, forbode the doom by showing the earliest signs of disintegration and thereby giving the greatest chances for recovery, by perhaps the abortive method of acclimatation or of rational nutrition.

Hope for the West.—The August number of the *North American Review* containing one of the contributions of Mr. M. G. Mulhall, the British statistician, quotes the percentage of illiterates in the Prairie States as being but 5.7 per cent. as against 6.3 per cent. in New England and 7 in the Middle States. This surprisingly favorable exhibit is attributable to the fact that the foreign settlers in the Prairie States are of a superior class to those in the Eastern, the former being mostly farmers from northern Europe, while the bulk of the latter consist of factory hands and unskilled laborers. May it not be assumed that the professions of the future have a better subsoil?

The Rational Employment of Defectives in Great Britain.—The *Popular Science Monthly* says: It seems that there are in England and Wales, 20,000 children so defective in mental powers that they are incapable, if left to their own resources, of fighting the battle of life. It is now proposed to take steps to provide a home for feeble-minded girls in West London. Dr. Warner, who takes great interest in the subject, says that since 1890 six homes have been started and kept going, the girl inmates helping to support themselves by laundry work and other occupations suited to their capacities. It is hoped eventually to have such institutions in all parts of England and Wales.

The Central Trend of Population.—At the recent Hygienic Congress Dr. Stephen Sedlaczek produced statistics of the increase in population of the greatest cities of the world since 1800. He showed some very interesting facts. The population of Amsterdam, Birmingham, Brussels, Manchester and Rome doubled in that period; Copenhagen and Marseilles have now a population three times as large as at the beginning of this century; London, Lyons, Paris, St. Petersburg and Prague have quadrupled in the number of inhabitants within the last ninety years; Breslau, Dresden, Hamburg, Cologne and Vienna have five times as many people; Leeds, Liverpool and Warsaw, six times as many; Glasgow and Sheffield, seven times as many;

Munich, eight times as many; Berlin, Budapest and Leipsic, nine times as many; Baltimore, ten times as many; New York and Philadelphia, twenty-five times as many; Chicago, 245 times, and Brooklyn 339 times as many as ninety years ago. Dublin, while slightly larger now than ninety years ago, has lost 17,000 inhabitants within the last forty years, and is the only large city in Europe which shows a retrograde movement in its population.

Psychic Phenomena.—One of the most remarkable manifestations of psychic force at the present day is the wave of suggestion that seems to sweep over the country periodically, affecting certain luminaries of the medical press on the subject of translations from foreign exchanges. In the first place, it is remarkable that out of the dozens of exchanges brought to these shores, the editors of some of our esteemed contemporaries should each happen to select the same articles for translation and condensation. But the mystery deepens as we note that some psychic force impels them to translate into brief abstracts, word for word, letter for letter, page after page, exactly as the articles were translated for the Journal the

tory.—There was much adverse comment when Governor Black vetoed the $250,000 appropriation for this Reformatory, but on petition, reviewing his judgment, he sent an architect to examine the building. The report returned is that the roof is necessary and should be constructed during the present season at a cost not to exceed $20,000. The contractors, and they are many, have expressed a willingness to go on without a formal appropriation.

The Muhlenberg Hospital of Plainfield, N. J., which was opened Dec. 1, 1881, and has a present capacity of only forty beds, is not large enough for present demands upon it. At the July meeting the Board of Governors, representing some nineteen societies, determined to make the possible additions as required.

Cincinnati.

The Mortality Report for the week shows: Zymotic diseases, 16; phthisis, 9; other constitutional, 15; local, 52; developmental, 9; violence, 9; stillbirths, 10; total, all causes, 110; annual rate per thousand, 11.12; under one year, 23. Deaths during preceding week, 97; corresponding week 1896, was introduced as evidence as having been treated by the defendant for "some trouble with the hip" whereas she was suffering from a tubercular hip joint disease. "Dr." Axtel while on the stand was subjected to a rigid cross-questioning, and showed himself totally ignorant of what the "school" to which he belongs claim to know so much. Judge Thompson took the case under advisement and has just rendered his decision, in which he fines the defendant $50 for practicing medicine without a license. With this decision as a precedent, the State Board of Health will leave no stone unturned in their efforts to rid the State of every practitioner of this form of quackery. The following is the Judge's opinion:

"The defendant is charged with 'practicing medicine' in this city without the authority required by the statute. It is urged by defendant's counsel that 'under the statutes of Kentucky the acts mentioned and complained of in the evidence do not constitute an offense.' That no witness has 'sworn that Axtel ever practiced medicine, ever gave a prescription or administered a drug, and it appears that he never performed any surgical operation, never used an instrument, never set a fracture, or did anything except to manipulate the limbs and muscles with the hands.' The legislature of Kentucky, in chapter 85, 'intended merely to make a law which would prevent persons from administering drugs or giving prescriptions who did not know anything about them.'

"The language of the statute is: 'It shall be unlawful for any person to practice medicine in any of its branches within the limits of the State who has not exhibited and registered in the county clerk's office in the county in which he resides his authority for so practicing medicine, as herein prescribed,' etc.

"It is not pretended that defendant has the authority to practice medicine which is prescribed by the statute. The only question, therefore, in the case is, Do the acts and doings of this defendant constitute the offense of 'practicing medicine' as denounced by the statute?

"This depends upon what the legislature intended by the words 'practice medicine.' If these words are to be construed as meaning only the administration of drugs, the giving of prescriptions and the performance of surgical operations, then this defendant is entitled to his acquittal. I think it is a just, and certainly a safe rule, to construe the language of a criminal statute in the sense in which it is commonly used and understood among intelligent people, and I do not think any person of ordinary intelligence ever uses *these terms in the restricted* sense here contended. The word 'practice' is defined by Webster to mean 'the exercise of an art, or the application of a science to the wants of men;' and the word 'medicine,' 'a remedial agent, a remedy, physic.' and in its secondary sense, 'that branch of science which relates to the prevention, cure or alleviation of diseases of the human body;' as the 'study of medicine' or a 'student of medicine.' It is in this secondary sense that the term 'practice of medicine' is always used among intelligent people, meaning the application of that branch of science which relates to the prevention, cure or alleviation of diseases to the wants of man.'

"The defendant claims that he applies to the prevention and cure of disease the science of osteopathy, which his advertisement defines to be 'the science of curing diseases without the knife or medicine.'

"The defendant puts in evidence the *Journal of Osteopathy* for May, 1897, in which Dr. William Smith, who seems to be an authority on the subject of osteopathy, writes of the 'three essentials.' He says: 'Were I asked to name these to the practitioner, no matter of what school, I would unhesitatingly state, anatomy, physiology and symptomatology.' Further on he says in italics: 'If you permit ignorant men to go forth and treat the sick and suffering, it is you who are responsible for their errors.' I find also in this journal, which seems to speak with authority, that osteopathy is a science; that it is based upon exact, definite and verifiable knowledge of the anatomy and physiology of the human mechanism, including chemistry, histology, morphology of its known elements, as make discoverable the great laws of the human system, by which nature, apart from artificial and medical stimulation, may recover from displacements, disorganization and consequent diseases, and regain strength and health.'

"From this evidence it is manifest that the practice of osteopathy is the practice of medicine within the meaning of the statute; it is further evident that no one is qualified to practice this branch of the science of medicine without a thorough knowledge of anatomy, physiology and the cognate branches which go to make up the science of medicine; and, upon the evidence, the court finds as a fact that the defendant has shown himself absolutely ignorant of the most rudimental learning in any of them. That in his ignorance of the fundamental principles of his profession, he subjected the child of Mrs. Detroy, which was laboring under a tubercular disease of the hip, to cruel and unnecessary torture, affecting its health and necessitating the employment of a physician to treat it for fever resulting from his inaptitude.

"The court is of opinion that any person who, for compensation, professes to apply any science which relates to the prevention, cure or alleviation of the diseases of the human body, is practicing medicine within the meaning of the statute; and as a matter of fact on the evidence, that defendant is guilty as charged, and the fine of fifty dollars is assessed against him."

Vacations.—A number of physicians of the city have left for their summer vacations. Dr. J. M. Mathews is sojourning at Makinac Island, Mich.; Drs. Clint Kelly and A. M. Cartledge are in Canada fishing; Dr. Louis Frank is at Petoskey; Dr. L. S. McMurtry will spend a week in Canada before going to the meeting of the American Association of Obstetricians at Niagara Falls; Dr. J. B. Marvin is at the Wentworth, Portsmouth, N. H.; Dr. J. A. Ouchterlony is at Atlantic City; Dr. Carl Weidner went to Germany to see his father, who had been in delicate health for some time, and since his departure last week word has been received by his family that the father died two days before he sailed, the letter apprising them of the fact being delayed in its transmission; Dr. J. W. Guest is at Rock Castle Springs, Ky., where he is the resident physician.

THE PUBLIC SERVICES.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from July 31 to August 6, 1897.

Lieut.-Col. Alfred A. Woodhull, Deputy Surgeon-General (chief surgeon, Hdqrs. Dept. of the Colorado), is granted leave of absence for one month and ten days, to take effect on or about Aug. 20, 1897.

Major Paul R. Brown, Surgeon, the order directing him to report for duty at Ft. Keogh, Mont., upon being relieved from duty at Ft. Hamilton, N. Y., is revoked.

Capt. William B. Banister, Asst. Surgeon, is relieved from duty at Ft. Crook, Neb., and ordered to Ft. Keogh, Mont., for duty.

Major Paul R. Brown, Surgeon, having been found by an Army retiring board permanently incapacitated for active service, will proceed to his home and await retirement.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending July 31, 1897.

P. A. Surgeon S. S. White, ordered to report on the "Concord" immediately.

Surgeon J. D. Gatewood, ordered to Brussels, Belgium, and Berlin, Germany, as delegate, then return.

Asst. Surgeon J. C. Thompson, ordered to the naval laboratory, New York.

Surgeon H. E. Ames, when detached from the "Cincinnati," ordered home and granted two months' leave.

Surgeon J. E. Gardner, detached from the "Amphitrite" and ordered to the "Dolphin."

Surgeon F. Anderson, detached from the "Dolphin" and ordered to the hospital, Yokohama, per steamer of August 14.

Surgeon H. G. Beyer, detached from Museum of Hygiene and ordered to the "Amphitrite."

P. A. Surgeon T. B. Bailey, detached from the "Machias" and ordered to the "Yorktown."

P. A. Surgeon J. S. Page, detached from the "Yorktown" and ordered to the "Olympia."

P. A. Surgeon G. Rothganger, detached from the "Pinta" and ordered to the "Wheeling" August 10.

P. A. Surgeon M. R. Pigott, detached from the "Olympia" and ordered to the "Machias."

CHANGE OF ADDRESS.

Davis, C. E., from Ann Arbor, Mich., to Woodward, Okla. Ter.
De Vaux, F. H., from Valley City, N. D., to Davenport, Iowa.
Harvey, D. M., from 1112 Folsom St. to 911 Laguna St., San Franc. Cal.
Lewitt, W. B., from 800 McAllister St. to 500 Van Ness Av., San Francisco, Cal.
McKee, C. W., from Chicago, Ill., to Cockran's Mills, Pa.

The Journal of the
American Medical Association

Vol. XXIX CHICAGO, ILL., AUGUST 21, 1897. No. 8.

ADDRESSES.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WARREN B. HILL, M.D.
MILWAUKEE, WIS.

The progress in medicine during the last fifty years has been such as to revolutionize its principles and practice. Empiricism has largely given way to rationalism, and physiologic and pathologic investigation has led to rational therapeutics. A great impetus has thus been given to pharmacy, while the experimental and physiologic laboratory has been the means of more accurate study into the physiologic action of drugs, and today we prescribe drugs with a degree of certainty as to their physiologic actions, little dreamed of by our earlier brothers in medicine. The advance in organic chemistry has enabled us to isolate the various active principles in remedial agents, so that it is possible, to a large extent, to produce physiologic effects by the use of alkaloids, unhampered by antagonistic and irritant substances which might be contained in the crude drug, thus bringing therapeutics to an exactness entirely inconsistent with former conditions.

Physiologic chemistry and advance in biology, has stimulated pharmacy in the line of synthetic chemistry, and today the laboratories of the world are busy producing new and sometimes useful compounds which are calculated to produce exact physiologic effects, based on the known actions of their chemic components. To mention the most conspicuous of these newer remedies would be tedious in the extreme, and to pass judgment on them, selecting the most useful, would be rash at this time, for the test of time is necessary and careful discrimination and experience will demonstrate their several virtues or shortcomings. The production of a number of useful and popular remedies of this kind has (unduly perhaps) stimulated energy along the line of multiplication of remedies, and the strife of the manufacturers has been such as to sometimes overlook the object, which is to produce something new and useful, and thereby earn for themselves a rich reward of fame and fortune—but rather to produce something which will sell, aided by the perfected art of advertising, which has (it seems to me) reached its acme in this—the closing decade of this our glorious nineteenth century. This evil tendency of multiplying pharmaceutic names, as well as remedies, is working mischief both in the medical and the pharmaceutic professions. The mercenary pharmaceutic chemist attacks his brother physician in his most vulnerable spot—his materia medica. He eliminates his necessity for remembering aught of incompatibles, and furnishes him ready-made compounds, with physiologic action and indications printed on the label, under a name that the chemist calls his own.

The mode of preparation of the remedy, as well as its exact composition, he retains as his own property, and it is a sad commentary on the progress of medicine during the last fifty years, that the record from the drug stores in the United States gives indisputable proof that the average physician (yes, a large majority of the profession, to a greater or lesser extent) encourges this baneful practice by his patronage. It demoralizes pharmacy, because pharmacists are no longer called upon to exert their knowledge and skill at compounding, but are required by the doctor, to put up so-called proprietary remedies, and their only care is not to make a mistake and put "B. J's." elixir when "J. B's." is called for.

At this rate of progress we will, in a short time, no longer need pharmacies, but commercial institutions, known as drug stores, will be all that is necessary. The commercial conditions into which pharmacists have been forced by a combination of manufacturing chemists and the doctors, has led to the evil of substituting, on the part of the druggist, and to a feeling of distrust on the part of the physician, who in turn incurs the enmity of the druggist by dispensing his own drugs by the aid of the manufacturing chemist, who kindly furnishes him, at wholesale, his favorite remedies put up in suitable vials already labeled for use. The ire of the druggist finds vent in counter-prescribing the very secret compounds which his former friend, the doctor, compelled him to have on the shelves.

Thus we see that the progress of pharmaceutic activity, in this one direction, has a tendency to alienate the two professions which are dependent upon each other and should work in harmony for the benefit of mankind. The remedy is simple. We are not to turn backward and ignore the progress in pharmacy and chemistry, but, on the contrary, we, as physicians, should amend our code of ethics so as to recognize *new* and *useful* remedies, and recognize the value of the time, knowledge and skill of those who, by their industry, bring to us the products of their labor. We should insist on the knowledge of the exact method of the preparation, its action, and composition of the product; and should extend to the discoverer the same rights of protection that we do to authors and inventors, and finally stamp out the secret nostrum man by a higher and more thorough education in materia medica and therapeutics in our medical colleges.

There was a time, not many years ago (when empiricism held sway), that therapeutics was the mainstay of the physician; but investigation has led us off into scientific and speculative fields, until now, in the field of medicine, the question of etiology and pathology are so all-absorbing that the treatment of disease is passed by with only a passing mention. While it is true that the enthusiasm and energy along these lines is what has brought medicine out of the depths of empiricism into the broad light of rationalism, it is necessary for us to bring back to its old estate the unpopular branch of therapeutics. For, after all, after we have learned to diagnose, detail the symptoms, talk learnedly of the etiology, the all-absorbing question to the patient is, "what are you going to do for me?"

We have the broad foundation of the years of investigation on which to build our structure of rational therapeutics, and we, as physicians, should join hands with our brothers in pharmacy, to provide a rational treatment for disease. There has been much done in this direction during the last few years. We have just entered on a new epoch in the history of therapeutics. Bacteriologic investigation has opened up new channels for thought and action, and today we have achieved a signal victory in the cure of disease by serum therapy. The remarkable result achieved in the treatment of diphtheria, by the use of antitoxin, has demonstrated that there is a legitimate field for investigation and discovery in this direction. The days of terror from the streptococcus seem to be numbered, as that serum is being so perfected that we have every reason to believe that in a short time erysipelas and kindred diseases will no longer resist treatment as they have in the past.

Tuberculosis is being attacked from several quarters, and tetanus and typhoid fever must, sooner or later, succumb to the treatment of antitoxins. Still, the field is large, the laborers comparatively few, and serum therapy is in its infancy. The use of toxins has been resorted to but little except experimentally on lower animals, but the time is at hand when they will be brought to their full share of usefulness. The human system may be made immune by the judicious use of toxins, the antitoxins being generated within the organism instead of being introduced from without, having been produced first in some other form of animal life.

The question now arises, "what is it that makes the serum antitoxic?" Can we not go farther, and, from the serum, isolate an active principle, as we did from Peruvian bark? Shall we not extend our chemic research into the realms of the animal organism, and find the antidote for the poisons generated within the human system?

These seem to me to be the vital questions of the day, and if we work with the same zeal that our colaborers have, in their investigation, we will have a new materia medica, a new pharmacy, a new therapeutics, that will attract the attention of not only the medical profession but of all humanity. For, it is here that disease will be robbed of its terrors, it is here that the acme of medical knowledge will be attained—the *cure* of disease.

DISCUSSION.

Dr. **WOODBURY** expressed the hope that biologic or organic chemistry would soon be able to isolate the effective constituents and present them as simple chemic substances, the dosage of which could then be definitely established and the physiologic actions of which could be investigated so as to place serum therapy on a scientific basis. The use of toxins for immunization appears to be a step in this direction.

Dr. **STEWART** recommended the reference of the address to the Executive Committee, and also to the American Pharmaceutical Association, which was agreed to.

Dr. **HILL** said that the remarks on the subject of toxins had called up in his mind, an interesting case of a man who had been accidentally rendered immune of erysipelas by the use of Dr. Coley's toxins from the streptococcus erysipelatis. The man was suffering with inoperable sarcoma of the neck. Rather with the idea of amusing the patient then with any hope of checking the growth, Dr. Hill resorted to injections of this serum. At first he used, daily, one injection of five or ten minims, which was sufficient to cause decided reaction including an eruption on the skin resembling erysipelas. The patient finally died, but what Dr. Hill wanted to bring particularly to notice was that he became so accustomed to the toxin that even the injection of ten cubic centimeters of toxin would produce no reaction whatever. He was absolutely immune to the streptococcus. He might be operated on without danger of pus formation; his abdomen might be opened and a pint of pus poured in and he would not have peritonitis, and he need not fear septicemia. It occurred to Dr. Hill that this condition was not due to stimulation of the leucocytes, or their increase in number, or to phagocytic action; but it was the fixed tissue cells which were modified in their functions by the toxin injections, then having caused a stimulation and incidental changes so that there was induced a special antagonism. A new set of cells was formed with the special function of generating antitoxin.

Two practical results came from this experiment. In that class of cases, where the patient after operation is especially liable to streptococcus invasion, not due to dirty surgery, but necessarily suppurating cases—if we are aware of this liability would it not be our duty to make the patient immune before we commenced the operation? The second thought is in reference to the action of the antitoxins in the system. There was, in his opinion, an alkaloid in the antitoxin, which did the work, and it is the proper field of analytic chemistry to discover and isolate this principle. We have known for fifty years or more, that a man may render himself immune to tobacco, or nicotin. How is this accomplished? It is brought about by the building up of a new set of cells of superior powers of resistance, and which secrete substances which make the system immune to the toxins. The same result follows the constant use of morphin, and a tolerance to the drug is established. It has been found that when a rabbit has become accustomed to morphin, and is not affected by a large dose, if we take the blood of this rabbit and inject it into another one, not thus accustomed to its effects, the blood will render the latter also immune to the usual fatal dose of morphin. Therefore, by this method, we have not only a means of counteracting the animal poisons, but also poisons of all kinds. It is in this direction of producing immunity from disease and protection from toxic agents of mineral, vegetable or animal origin, that clinical medicine has a most promising field before it. The workers in the department of bacteriology have done their share; it is our duty to take up the work where they have left off and isolate the remedial agents and determine their physiologic actions and therapeutic applications.

ADDRESS OF WELCOME TO DELEGATES FROM THE AMERICAN PHARMACEUTICAL ASSOCIATION.

Delivered in the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WARREN B. HILL, M.D.

MILWAUKEE, WIS.

Gentlemen of the American Pharmaceutical Association:—We feel honored by your presence here today. The significance of the meeting of the representatives of the two great professions or, rather, the two branches of the one great profession of medicine, is well worthy of consideration.

Thoughtless men little realize how closely the professions of pharmacy and medicine are bound together, how dependent the one is upon the other, and yet how seldom we come together for our common weal. There is a tendency toward estrangement rather than that coöperation which should exist between the two, and the only way to overcome this estrangement is by coming together and cementing our friendship with united work.

The pharmacist is the right hand supporter of the doctor. He is especially fitted for his part of the work, and without his support, the doctor would indeed be in a sorry plight. The perfection of our armamentarium depends on our fellow laborer in the pharmaceutic profession. The leaders in your profession have in the past and are at present giving their best efforts to bring pharmacy up to the highest standard of professionalism, where it rightfully belongs, but they are hampered and impeded in their work by the commercial druggist, who with the aid of the commercial doctor are the means of disseminating nostrums broadcast throughout the land and bringing down from its high estate the practice of medicine and pharmacy.

The danger of commercialism in our profession is patent to every observant mind, and it should call forth a stronger effort on our part toward a united action in the progressive work in which we are engaged. The Section of Materia Medica, Pharmacy and Therapeutics, gives us a place in our National Association where we may come together, and bring to each other the results of our work and investigation; a place to cement our friendships and receive fresh enthusiasm in our common work.

I wish to honor your colleague, Prof. Rusby, for the work he has instituted in the "joint investigation," a work that can not be over estimated, and now, having been instituted, should be carried on and developed to such an extent in the future that its power and influence should be felt in the medical world. I would suggest that each of us go to our homes with the importance of this work so impressed upon us, that we use every effort to establish such a system of collaboration in the State societies to which we belong, and bring our State pharmaceutical and medical societies into closer contact.

I, therefore, welcome you, delegates from the American Pharmaceutical Association, to our society as co-laborers. I welcome you to the work in which we are engaged in the practice of medicine, and I trust the day is not far distant when your profession will not be looked upon as something apart from ours, but regarded as one of the settings in the grand mosaic that goes to make up that noble profession which disregards self in the work of alleviating suffering and restoring physical man.

RESPONSE BY F. W. STEWART.

Chairman of the Committee from the American Pharmaceutical Association.

It gives me great pleasure to respond to your address of welcome on behalf of the delegation from the American Pharmaceutical Association. In making this response, I desire to call your attention to the fact that this delegation, consisting of thirty-one leading pharmacists, representing every section of the United States, is here by invitation of the AMERICAN MEDICAL ASSOCIATION. The object the ASSOCIATION had in extending an invitation to the National Association of Pharmacists to take part in the deliberations of the National Association of Physicians was, and is, the recognition of pharmacy as a part of medical science and practice; not the recognition of commercial pharmacy by the commercial physician, but the recognition of professional pharmacy by the professional physician.

The professional physician, in thus recognizing pharmacy as a part of medical science and practice, requires that the pharmacist shall comply with professional requirements; and the delegation of the national organization of pharmacists, by its presence here, admits that pharmacy should be practiced with the same beneficent object as medicine.

Medicine is not only a liberal and beneficent profession but it is a fraternity as well. From the earliest times the medical profession has been a fraternal organization. We still believe in the Hippocratic oath and its obligations. The physician must, therefore, serve his profession, and his standing in the profession should depend upon the manner in which he meets his fraternal obligations. It is, therefore, considered unprofessional for a physician to withhold the knowledge of discovery from his professional brethren for the purpose of obtaining advantage over his fellows in practice. Furthermore, the practice of medicine is dependent on progress in the knowledge of disease and the methods for treating those afflicted with disease. This knowledge, published in medical literature, and classified in scientific forms, constitutes the science of medicine. The service of the professional physician is, therefore, toward the cause of suffering humanity, the cause of public health, the cause of the professional brotherhood of which he is a member, and the cause of medical science. As a member of the subsidiary profession of pharmacy the pharmacist is bound by similar obligations to humanity, to science, to his professional brethren and to the medical profession.

You have heard that the pharmacist is the servant of the public. So he is; but his contact with the public should be through the physician and under the guidance and control of the medical profession. The preparation of medicine must always be subservient to the application of medicine to the treatment of the sick; therefore pharmacy is subservient to therapy; and the pharmacist is subservient to the physician. He is not educated to practice medicine and should leave that important and responsible vocation to the physician. This does not apply to the pharmacist who is also a physician, though the practice of both pharmacy and therapy by the same individual is objected to by some. The pharmacist owes it to the physician, with whom he is, or should be, in fraternal relations, not to interfere with the physician's prerogatives on the one hand; and he is under obligations on the other hand to discountenance those who do so interfere.

The vocation of the professional pharmacist is, therefore, to aid the physician in his efforts to combat disease, by working hand in hand with him as his professional brother, devoting himself to the study of drugs from every possible point of view, and furnishing the same in the form of scientifically prepared pharmaceutic preparations with published formulæ and open methods of manufacture.

But if we are to have a profession of pharmacy devoted to the service of the medical profession as the "physician's right-hand supporter and co-laborer," as you have said, the medical profession will have to foster and protect such professional pharmacists in the pursuit of their profession. There is only one way to do this, and that is to throw the patronage of the profession into the hands of those pharmacists who practice pharmacy professionally.

The medical profession can not be blamed for withholding its patronage from druggists who prescribe over the counter, renew prescriptions without the sanction of the prescribers, and manufacture and sell nostrums. Under the existing state of affairs the physician may be justified in dispensing his own medicines to protect himself and his patients from such irregular practices. But I claim, as the representative of the delegation of the American Pharmaceutical Association, that the medical profession itself is more responsible than the pharmacists for the disgraceful state of pharmacal practice, for by prescribing nostrums of secret and secret composition, and patented medicines until, in some localities, about one-half of the medicines prescribed are of a secret or proprietary nature, physicians have forced pharmacists to keep such medicine in stock to supply the very demand the physicians themselves have created. Educated and professional pharmacists everywhere deplore the condition of affairs, but are powerless to prevent it. The reform must come from the medical profession itself. Let every physician refuse to prescribe medicines controlled by patents, secret formulas, and so-called trade-marks, and send their prescriptions to professional pharmacists who practice pharmacy under professional and scientific requirements, and the nostrum trade would soon be forced back to the lowest depths of the infernal regions from whence it came. Then let the two professions come to some proper understanding in relation to the sale of such open formula household remedies for certain minor ailments. for which the public will always patronize the drug store, and we will have secured the desirable object so well described by the Chairman in his very able address.

ORIGINAL ARTICLES.

ON THE THERAPEUTIC PROPERTIES OF ALCOHOL AND THE REASONS WHY THE FERMENTED AND DISTILLED LIQUORS USED AS BEVERAGES SHOULD NOT BE RECOGNIZED IN THE PHARMACOPEIA AS MEDICINAL AGENTS.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics at the Forty eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY N. S. DAVIS, A.M., M.D., LL.D.
CHICAGO.

Pure ethyl alcohol, undiluted, is regarded by all chemists and intelligent physicians as an active poison, rapidly destructive of both vegetable and animal life whenever brought into contact with either. The presence of absolute alcohol in contact with any living tissue immediately arrests all natural metabolic and vital processes in such tissue, and causes it to become corrugated or shrunken and dead. Swallowing absolute alcohol, undiluted, as quickly destroys the vitality of the membranes of the mouth, throat and stomach, and kills the individual, as does pure carbolic acid. Consequently, alcohol, in its pure and undiluted state, is not capable of being used as a medicine, but when largely diluted with water, as it is in all the fermented and distilled beverages, its direct corrosive or corrugating effect upon the membranes it comes in contact with is so much diminished that it is capable of being absorbed and conveyed in the blood to all parts of living body. In this diluted condition, therefore, it early began to be used both as a medicine and as a popular drink, and as the most readily appreciable effect was to diminish the individual's consciousness of impressions, not only from without but also from within, it soon came to be regarded as a universal tonic and restorative. Its supposed tonic and restorative effects were based wholly on the sensations and movements of patients or individuals under the influence of moderate doses, for it was soon demonstrated that large doses directly diminished strength, sensibility and action. But when under the influence of moderate doses the patient said he felt less weak, or weary; felt the sensation of cold or heat as pain less, felt lighter or more buoyant and his heart was found to beat faster, it was perfectly natural for both physician and patient to think the alcohol was acting as a tonic or stimulant and general restorative. It was not until the advancement in analytic chemistry and the physiology of all parts of the nerve structures of man, coupled with the researches of physics and biology of the last half century, that we have had it in our power to prove the incorrectness of these conclusions founded on the sensations and actions of the patient under its influence. The more recent chemico-physiologic researches have shown more clearly the composition of the blood and the various tissues of the body, and especially the existence and functions of the hemoglobin, leucocytes and other corpuscular elements of both blood and tissues, and the part each plays in the reception and internal distribution of oxygen with its effects on all the metabolic changes in living bodies. By the same class of researches it is shown that alcohol, diluted with water and taken into the stomach, is rapidly absorbed by the capillaries and is conveyed in the blood to every tissue in the body and by its presence retards the natural metabolic changes, lessens the processes of oxydation and elimination, diminishes nerve sensibility and, when repeated from day to day, induces cell and tissue degenerations. By the more recent studies in the anatomy and physiology of the several parts of the nervous system it has been shown, not only that the action of the heart and the movement of the blood in the vessels are directly under the control of the cardiac and vasomotor nerves, some of the fibers of which are excitors of action while others are inhibitors, by which uniformity and harmony is maintained in the circulation of the blood, but also that our voluntary movements and sensations are manifested by the cerebro-spinal nerves, having their excitors and inhibitors by which we are enabled to co-ordinate muscular contractions and relaxations in executing all complex movements, and equally so it is that our mental actions, manifested through the convolutions of the brain, are regulated by excitors and inhibitors. Every individual whose brain is in its normal condition has frequent sensations, impulses or excitors of mental actions which he promptly inhibits or disregards. Indeed, it is on the proper development of this mental inhibition that every person's self-control and sense of propriety depends. If it is true, as has been already stated, that alcohol when taken into the living system in large doses is an active poison, quickly destroying animal life, and in smaller doses is an anesthetic directly diminishing cerebral sensibility and mental consciousness and retarding all metabolic changes, both in the blood and tissues, it follows as a logical and necessary inference that if administered as medicine it should be done with the same care and exactness in regard to purity, dose and time that we exercise in prescribing morphin, quinin, aconite, arsenic or any other active drug. This can not be done by using any of the various fermented and distilled liquors ordered either from drug stores or liquor dealers, since they are kept at no uniform standard of either strength or purity. The present pharmacopeia recognizes as medicines, vinum or wine, spiritus frumenti or whisky and spiritus vini gallici or brandy, but does not give a definite officinal standard of alcoholic strength for either of them. Neither does it give any reliable and readily available tests by which the strength and purity of the articles can be determined by the ordinary practitioner of medicine. Repeated analyses have shown that the amount of alcohol in different samples of wine varies 6 to 25 per cent.; in whisky from 35 to 50 per cent.; and in brandy from 40 to 60 per cent. Such variations in the strength of any other medicine would quickly cause its standard to be corrected or its exclusion from the official list of drugs. As alcohol is the only important therapeutic agent in all these liquors, why not let pure alcohol of fixed strength be officially recognized to the exclusion of all the varieties of both fermented and distilled drinks. Then every practitioner desiring to give alcohol as a remedy could order it with any desired degree of dilution with water and he would know what his patient was getting and how much, and the pharmacist would no longer have need to pay for a license to sell liquors or to be classed with the ordinary dealers in such beverages. One of the most important improvements in modern pharmacology consists in the separation of the active therapeutic agents from the more complex or crude drugs and thereby enables the physician to administer them with far greater convenience and certainty. Very few intelligent physicians of the present day would think of prescribing crude opium when they desired to produce only the anodyne effects of the morphin it contained, certainly not without knowing what per cent. of morphin would be in the crude drug. Why, then, should he prescribe the uncertain mixtures called beer, wine, whiskey or brandy when his sole object is to obtain the therapeutic effects of alcohol? If it is claimed that these several fermented and distliled liquors contain other therapeutic agents in addition to the alcohol, we answer that, so far as any such agents exist, their proportionate quantity and quality are far more variable and uncertain than is their per cent. of alcohol. Almost the only constituents found in whisky and brandy, besides the alcohol and water, are very variable quantities of fusel oil, tannin and, in very old specimens, a trace of some etherial substance to which connoisseurs attribute the special *bouquet*. So far from adding to the therapeutic value, the first two substances are regarded as very undesirabte impurities and the last named has never been isolated in sufficient quantity to have its medical qualities tried. Much has been said and written concerning valuable nutritive constituents in the different varieties of wine, but the numerous analyses on record show only very variable quantities of fecula, saccharin matter, tannin, some vegetable acids and potassium salts, in addition to the alcohol and water. Of these extra ingredients the fecula and saccharin matter are the only ones that could be classed as nutritive or capable of being converted into any natural element of the blood or tissues of the body. The quantity of these in any variety of wine is so limited that it would require several barrels of the wine to furnish the equivalent of a pound of bread. Consequently it would be far more economic as well as more scientifically accurate for every physician to prescribe such doses of pure alcohol and water to be given with such quantify of sugar, milk or meat broth, as he thought his patient might need. The physician who can not do this and thereby accurately adjust the proportion of all the elements his patient may need has certainly received a very defective profesional education. It would be a long and very important step in advance both in the interests of scientific accuracy and of humanity if all physicians when they thought alcohol was needed would prescribe it in the manner just indicated, and if in the next revision of the pharmacopeia only alcohol of standard strength was retained to the exclusion of all fermented and distilled liquors. If these changes were adopted and carried into general practice the result would be a more complete separation of both pharmacist and physician, from connection with or responsibility for, the general traffic in and uses of the various alcoholic liquors in popular use.

DISCUSSION.

Dr. **Frank Woodbury** said that about twelve years ago he had adopted the plan recommended in the paper of substituting diluted alcohol for all forms of alcoholic stimulants in his service in the medical wards of the Medico Chirurgical Hospital, which had been previously suggested by Dr. Dennis of New York. He had used high wines or cologne spirits in water flavored with peppermint or cinnamon. The accuracy of dosage and the absence of all deleterious flavoring substances seemed to make this the preferable method of administering alcohol, at least in all public institutions. As regards the physiologic question, whether or not alcohol increases the energy of the body, it is sufficient to recall the fact determined by Dr. Edward Smith that the excretion of carbonic acid is diminished by spirits, such as brandy or gin, which also diminish the excretion of urea. As bodily force must come from combustion and increased metabolism in the organism, it is evident that alcohol is a force producer only within the limits of its oxidation, and any excess of this small quantity retards waste and checks force production. In therapeutics alcohol is a food, a stimulant to the circulation, a nerve sedative or a narcotic, according to circumstances and dosage.

Professor **Remington**—As a member of the Committee on Revision of the Pharmacopeia, I think it is only right to state the method which is in vogue with the Committee for introducing various drugs and medicines into the pharmacopeia, and for dropping from the official list such as are undesirable. This is left exclusive to the physicians on the Committee, to whom are intrusted the task of selecting and deciding on the claims of substances and preparations which are proposed for admission into the national pharmacopeia. Now, their action is very largely regulated by the demand and the use of these drugs and chemicals. If they are much used they are retained but if there is no demand by physicians they may be dropped. On my part, I can see no very great objection to the dropping of spiritus frumenti and spiritus vini gallici from the pharmacopeia because they do not enter into any official preparations, but as regards vinum album and vinum rubrum, this would be scarcely possible because they do enter into the composition of preparations such as the wine of ipecac or wine of antimony, for instance, which are official. Therefore it is absolutely necessary for the pharmacopeia to limit the amount of the alcohol and determine the purity of wines and to prescribe tests for determining the value of wines. In the pharmacopeia of 1880 there were very good alcoholimetric tests to ascertain the strength of wines. It is very necessary for the pharmacist to know the exact amount of alcohol in the wine, because if it is deficient in strength the preparation will not keep and if, on the contrary, it is too strong it would become like a tincture and defeat the medical object in view in selecting the wine as a menstruum.

Granted that alcohol is a curse, and I am thoroughly in accord with Professor Davis in his desire to restrict its use, but, granting this, should there not be some authority in the country to decide what shall be dispensed by the druggists when the doctor's prescription calls for wine or brandy? How shall the pharmacist know what is in the mind of the physician when he uses these terms? On the other hand, if such a practical test as Dr. Davis prescribes can be put into the pharmacopeia—though I am not sure this can be done—it would result in this, that it would be in the power of various druggists throughout the country and boards of health everywhere to decide on the tests for purity and strength and there would be no uniformity. If it were a question of driving all alcoholic drinks out of the country, that would be one thing; but, if this is not feasible, would it not be better to have some control over those that are to be used in medicine. The question raised by the paper certainly needs some attention, but should we not desire to make the tests more exact and the regulation more stringent rather than to leave it without any control whatever? Dr. Rice of the Committee on Revision some years ago received a number of communications from the Western States about the wines and brandies not being up to the standard and suggesting that the standard of the pharmacopeia be made easier of application, and we have now under consideration such a test, which will give more definiteness to the strength. As regards the Committee, I would say that the Committee on Revision are not altogether responsible for the presence of spirtus vini gallici and spiritus frumenti in the pharmacopeia; they are only there because there is use for them and physicians use them. I would, personally, very much prefer to send every one who wants brandy or whisky to a store where spirits are regularly sold, and so would every member of the Committee on Revision, but as long as they are employed for medicinal purposes there must be some standard established by authority, that is to say, the pharmacopeia.

WM. THOMPSON, Washington, D. C.—As a pharmacist I am honest in this question. I am anxious, if possible, to leave the drug store no excuse for dealing in alcoholic liquors and selling brandy and whisky. As one means of preventing this abuse as far as possible I am anxious to see these two articles dropped from the pharmacopeia. It is not for the profession of pharmacy or for the pharmacist to say that these articles are worthless. Spiritus vini gallici, spiritus frumenti, vinum rubrum and album, we have just been told, are valuable only for the alcohol they contain, and this has been my own opinion for a long time. I am glad to have the authority of Dr. Davis for the statement that the physician, when he desires to prescribe any of these articles, may get the same effect from the use of dilute alcohol. Moreover, when he orders alcohol diluted with clean water the physician knows just what quantity of pure alcohol the patient is getting, but when he gives spiritus vini gallici and spiritus frumenti he gives an uncertain quantity of alcohol, combined with certain ingredients which are added to make the preparation palatable, and there is danger of creating an appetite in the patient for these alcoholic drinks. This danger does not attend the use of dilute alcohol because it is not palatable. I do not agree with Professor Remington that it is necessary to have them in the pharmacopeia so as to establish some standard of purity; if they are not to be used in the treatment of the sick they should not be in the pharmacopeia. As to the difference between brandy and whisky, if the patient is not a connoisseur and experienced in the matter, he can not tell the difference by any chemic means. As regards vinum album and rubrum, the small amount of alcohol could be supplied by using dilute alcohol, and by using this the preparation could be made just as well as they could from the use of vinum album or rubrum.

Dr. J. V. SHOEMAKER—I fear that I can add nothing to the very full consideration of physiologic action and the practical recommendations which Professor Davis has given with regard to the use of alcohol and the elimination of wines and spirits from the pharmacopeia. Some years ago, while I was writing on the subject of alcohol and endeavoring to describe the differences between brandy and whisky and the different wines, I sought information from a gentleman who was employed in one of the large manufacturing establishments and he told me that if he had given to him a certain amount of alcohol and certain flavoring ingredients and coloring materials he would make a most perfect brandy or whisky, the most perfect white wine and red wine the most expert gourmet would want to taste. Now, as thus distinctly formulated and as already stated by the distinguished speaker, we are pouring into our patients certain extracts and flavoring substances in order to get the action of the alcohol. Many years ago I adopted the use of alcohol in the dilute form as a substitute for the officinal spirits and was satisfied with the results. As one of the humble laborers in this Section, I add my voice to that of Dr. Davis in favor of dropping the spirits and wines from the pharmacopeia and to make alcohol alone the officinal preparation.

Dr. KEEN, Pittsburg—It is a fact that perhaps 75 per cent. of all practitioners of medicine in the United States will continue to use whisky in their practice during the next ten years, whether the pharmacopeia recognizes it or not. Professor Remington, on behalf of the pharmacopeia committee, stated that no drug that is used so commonly as is whisky could be dropped from the pharmacopeia. He also stated, and I agree with him, that there should be some standard of purity for articles that are used in medicine. I therefore think that whisky should not be taken from the pharmacopeia. I believe that whisky is capable of doing good; I have seen life saved by it. It is no reason that it should be thrown out of the pharmacopeia because it may be abused. We might as well throw out opium or morphin because some people form an opium or a morphin habit. In my opinion the opium habit is a greater curse to society than the alcohol habit. To drop whiskey from the pharmacopeia would do no good. It would still be prescribed by physicians and there would then be no standard of quality or of therapeutic activity. That is the question in my mind.

Dr. ECCLES—Dr. Keen has just informed us of his knowledge that life has been saved by the use of whisky, and that 75 per cent. of professional men would use whisky during the next ten years whether the pharmacopeia recognize it or not. I do not know whether or not whisky, as such, is much prescribed throughout the United States, but in the section of New York in which I am situated the druggists will scarcely receive one prescription for whisky in twelve months, and this is the general experience of pharmacists in my neighborhood. If this is then the case, that whisky is so frequently prescribed in Pittsburg, where Dr. Keen comes from, it is a very remarkable state of affairs. Professor Remington has stated that it would be necessary to retain the officinal wines. I believe that there is no value to be obtained from the wines which we can not get as readily from dilute alcohol. It may be objected that the preparations made with alcohol would not be so palatable, but as Dr. Shoemaker has told us that in nine cases out of ten even experts may not be able to distinguish the prepared wines from the pure article, it is evident that the palatability is due to flavoring ingredients, which may be added, if desired, to the dilute alcohol. The impression is becoming general that the druggist's is not the right place from which to get brandy or whisky, but the applicant should go to the liquor store. The liquor dealer can afford to sell liquors cheaper in small quantities, and druggists should direct their patrons to the liquor store for brandy or whisky, and in this way he does not promote in any way the abuse of these articles by the public. Professor Remington has stated that if they were dropped from the pharmacopeia there would be no standard of purity, but other articles are constantly prescribed which are not in the pharmacopeia; antipyrin, for instance, and other drugs of the coal tar series. The tendency of evolution is to go to the active principle of remedies, as the vegetable alkaloids, and why should we not do this in the case of whisky? We no longer prescribe opium, cinchona and other crude drugs, but use morphin, codein and quinin or cinchonin. The alcoholic drinks are used principally for the alcohol. The drug stores are loaded up with wines of coca and other wines not in the pharmacopeia. I am very much in favor of making those of alcohol pure and simple. I can not go as far as Dr. Davis does, in believing that alcohol is not destroyed in the system. I believe that there are temperance reformers who use alcohol every day. I believe that *it is formed in the process of digestion in the intestinal tract.* I do not wish to be misunderstood. I would not prescribe alcohol when it is not needed simply because it is formed in the intestinal tract, any more than I would prescribe pepsin where it was not required, which is also found in the alimentary canal.

Dr. C. C. FITE—I would say to the members of the Committee on Revision, that the further they go away from the physicians' prescriptions in the pharmacopeia, the farther the physicians will go away from the pharmacopeia.

Dr. KING—I would like to reply to Dr. Eccles' statement that Pittsburg has a very remarkable state of affairs, and to say that I am led to believe that the physicians in Brooklyn have very little faith in their druggists. Now we do believe in our pharmacist and send to him for all our drugs, including whisky and brandy. I never prescribe antipyrin or any other article which is not in the pharmacopeia.

Dr. F. E. STEWART—On behalf of the delegates from the American Pharmaceutical Association, I desire at this time to offer the following:

WHEREAS, The medicinal properties of spiritus frumenti and spiritus vini gallici are due solely to the alcohol they contain; and alcoholic stimulation can be better achieved by the use of pure alcohol properly diluted and with less danger of the patient acquiring an alcoholic appetite, than by administering either of the above-named beverages; it is, therefore

Resolved, That the Section on Materia Medica, Pharmacy and Therapeutics of the AMERICAN MEDICAL ASSOCIATION recommends that spiritus frumenti and spiritus vini gallici be dropped from the United *States Pharmacopeia in its next revision.*

This was adopted by the Section.

Dr. DAVIS—I hope that I made it plain that I raised no question in the paper as to the value of alcohol as a medicine. I simply spoke of its physiologic properties and spoke of the desirability, for those who wish to use it, using it in its purity and knowing exactly what they are using. I made no question as to whether life is saved or life is destroyed; no question whatever. There are thousands of druggists who do not wish to be classed with liquor dealers, and would like to put it out of their shops.

FURTHER DISCUSSION.

Discussion on the Subjects Referred to the Section on Materia Medica, by the American Pharmaceutical Association.

Dismissal from the United States Pharmacopeia of spiritus frumenti, spiritus vini gallici, vinum album and vinum rubrum; replacement of officinal wines by vinegars; dismissal of all tinctures having a fluid extract of the same drug officinal; substitution for such tinctures and fluid extracts of a 50 per cent. tincture under a distinctive title; change of formula for Dover's powders back to that of the 1890 United States Pharmacopeia, by using potassium sulphate in place of sugar of milk.

Professor Remington—I have very decided views on these subjects of dismissal of spiritus frumenti and vina from the pharmacopeia and the replacement of officinal wines by vinegars, and I think that in both cases they are in the negative. The former subject has been considered and, as regards the latter, while I believe that the vinegars are useful and that the class could be increased with advantage, yet as regards the substitution of vinegars for the officinal wines, I do not think it can be done. For instance, the wines of ergot, of iron, of antimony, are very largely used in the United States, and the great objection to the dismissal of agents which are in use by physicians is that we thereby increase the number of drugs used over which we have no control. I therefore think that there can be no ground for the dismissal of the wines from the pharmacopeia. In the proposed dismissal of tinctures and fluid extracts we have the same difficulty before us. Physicians will continue to prescribe tinctures. We have supplanted a good many by fluid extracts, but physicians do not use them; for instance, digitalis. We have supplied for thirty years a fluid extract, but physicians have not yet abandoned the use of the tincture. Then again, there is the objection of the difference in the strength of the proposed 50 per cent. tincture and also in the menstruum. We now have dilute alcoholic preparations in the tinctures, strong wines and fluid extracts, and this proposed change would add another. If the doctor wishes to get the full action of all the active principles of a drug he would order the tincture, because the menstruum used in the tincture extracts more than other menstrua, because by adding water to some of the tinctures you will have a precipitation and the solution loses some of its effects.

With regard to the distinctive title of these proposed preparations. The question in regard to the fluid extracts has been before the Committee on Revision for thirty-five years. The tendency is to increase the strength so as to make them conform to the standard of one grain to the minim; rather than to reduce it. The fact of making the fluid extract weaker would open the door to sending out fluid extracts of half strength. The question came up before the Committee on Revision in 1880 and again in 1890, and has been referred to a subcommittee to work on. It was also discussed at the last meeting of the American Pharmaceutical Association. With regard to the substitution of sugar of milk for the potassium sulphate in Dover's powder, which was first suggested by Dr. Piffard, and the proposition to change it again, I think that the old method is the better one, and would approve the change. This subject was fully considered by Mr. Kebler in the June issue of the *Druggists' Circular*.

Dr. C. C. Fite moved that the Section does not concur in any of the above suggestions sent to it by the American Pharmaceutical Association, except in that with regard to Dover's powder. This was unanimously adopted.

ANTITUBERCULIN.

Presented in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY JOSEPH McFARLAND, M.D.

PHILADELPHIA, PA.

The enthusiastic reception of the "Blutserumtherapie" led many of our esteemed colleagues to entertain the most ardent expectations of miraculous results in all divisions of the field of infective diseases. The constantly increasing number of recoveries from diphtheria that were reported and the occasional recoveries from tetanus that were hurried into print, convinced large numbers of professional, as well as lay men, that "Blutserumtherapie" led to an almost unlimited field of usefulness.

In those early days, I was frequently asked what the chances of serum treatment were likely to be and why I did not hasten to occupy that field and be among the first to benefit mankind with that much-needed boon, a "cure for consumption.". My answers to these inquiries were received with incredulous looks, and my endeavors to show why serum therapy for tuberculosis was likely to fail in the majority of cases, were unheeded. It was only after several years had rolled by and I had been almost forced into the field, that I at last consented to undertake the experimental research in which a number of the gentlemen present have so kindly aided me.

In order to make clear my grounds for hesitation and my convictions that the experiments would fail, I beg your indulgence in a brief résumé of the pathology of tuberculosis: Tuberculosis is primarily an inflammatory process. Every tubercle begins its history as a single inflammatory node, not very different from those produced by the introduction of foreign particles into the tissues. In the early stages of the disease there is rarely any marked systemic involvement, and many cases progress to the considerable destruction of organs before constitutional symptoms are observed.

Up to a certain stage, therefore, tuberculosis is not essentially different from any ordinary or non-specific focal inflammation. It is as the disease progresses that the difference is observed, for as the cause of the disease is alive and engaged in growing and propagating its kind, there is a progressive tendency for the disease-producers to disseminate and new inflammatory foci to form, and as growth means metabolism, there are waste products of the growth to be absorbed and eliminated. This is by no means all of the pathology of the disease. The tubercles develop at the expense of the organs whose tissues transformed into or replaced by the tuberculous tissue, are unable to perform their functions, or do so so insufficiently that disease must result from their incomplete action.

Lastly, the tuberculous nodes in which no blood vessels are formed, constantly soften and disintegrate with the frequent formation of holes or cavities in the tissues, in which, if they communicate with the outer air, saprophytic bacteria are likely to grow and add the harmless or oftener harmful results of their metabolism to the blood.

Tuberculosis is thus a progressive, distributive and in most cases, essentially chronic disease, from which death is more often the result of the destruction of organs, suspension of vital functions from local lesions, and profound secondary anemia, than from any poisonous principle in or produced by the bacillus. Viewed from such a standpoint, and this is the standpoint I always took in the early days of serum therapy, what could any antitubercle serum do? Could it reinstate disorganized organs? Could it prevent secondary infection? Could it prevent the dissemination of the bacilli in the organs or could it probably kill the bacilli already in the body? The last two questions are admittedly possibilities, and to them a third possibility might be added, the serum might excite the normal vital resistance of the animal body so as to enable it to dispose of the bacillus by phagocytosis or its bactericidal humors and so render it harmless. These seemed to be the possibilities, but the insurmountable difficulty seemed yet to c[illegible] t woul[illegible] an antitubercle serum be? How [illegible]

Clinicians.	Age and sex.	Occupation.	Stage of Disease.	Condition on beginning treatment.	Duration of treatment.	Dosage.	Disadvantages.		Comments.
Ed S Reynolds and J. C. Welch.	F.	. . . .	Advanced.	. . . .	About a month.	5 to 100 m. daily.	Cramps in the lumbar and gluteal muscles and much pain.	Cough and expectoration diminished	Patient died. "There were no results to encourage the use of the serum."
Ed. S. Reynolds and J. C. Welch.	M. 27.	. . . .	Advanced; 7 years old; confined to bed when treatment was begun. Had been housed for months.	Weight 120; hectic; temperature 97-100½° F.; cough moderate but troublesome at night; marked physical signs; night sweats; diarrhea.	Six or eight weeks.	. . . . .	Urticaria in every part of the body, one attack only. No repetition or other bad symptoms.	Night sweats ceased; cough improved; temperature was reduced in two weeks to 98.6-99; diarrhea ceased; appetite improved; weight increased to 125; became able to walk out to a distance of a half mile; pulse and respiration became normal.	"The serum has done wonders." Dr. Reynolds feels that it will effect a cure in this case.
James M. Anders.	. . .	. . . .	First stage.	. . . .	Short.	. . . . .	None mentioned.	None given.	Encouraging success.
M. R. Ward	. . .	. . . .	Third stage.	Temperature 102-103° F.; pulse 115-120.	Three weeks.	. . . . .	. . . .	Temperature dropped to 100-101; pulse subsided to 96-105; appetite improved.	Patient became worse when the treatment had to be suspended because the supply failed. Two cases treated with Paquin's serum recovered.
Guy Hinsdale. . .	F. 27.	Married; housekeeper.	One year old.	Weight 120 pounds; cough and night sweats; physical signs marked; many tubercle bacilli.	Four months.	5 to 40 m.	None noted.	Weight increased to 127; bacilli disappeared; all physical signs disappeared except slightly increased vocal resonance over the right apex.	This case seems to have recovered. Dr. Hinsdale promises to make a future report of the case.
A. A. Eshner. . . .	F. adult	Married.	Probably three years old.	Cough; loss of weight; impaired appetite and digestion; constipation; weight 138.	Nearly three months.	1 to 2 c.c.	None noted; there was some discomfort, no pain following the injections.	Temperature was not altered, as it had not been elevated; no distinct effect on pulse or respiration; body weight increased to 112; appetite and color of skin improved; chilliness ceased after beginning the injections; physical signs did not improve.	Concludes that while the serum did no good it certainly did no harm.
J. S. Cohen.	F. 23.	Married; three children.	Probably four years old.	Night sweats, cough and expectoration; weight 120 pounds; marked physical signs; tubercle bacilli in sputum.	Jan. 9 to Feb. 14; recovered after three weeks.	. . . . .	. . . .	Cough lessened during treatment, became worse when treatment ceased; when treatment began again some favorable signs observed. Patient was discharged from the hospital April 1, 1897, weighing 118 pounds.	Seems to have done good.
J. S. Cohen	F. 21.	Single.	Four months.	Cough troublesome; t. b. in sputum; marked physical signs.	Began Jan. 10 to Feb. 12, '97.	. . . . .	Urine decreased markedly in amount and showed traces of albumin.	Strength and appetite decreased; when the treatment was stopped patient improved.	Seems to have done harm.
T. V. Crandall . .	F. 26	Secretary.	Since Oct. 10, 1895	Pulse rapid; temperature 103; expectoration of blood and pus followed by cavity formation; cough constant; expectoration 63 in twenty-four hours; tubercle bacilli.	Began June 6, 1896, with Paquin's, concluded with Mulford's.	Up to 30 m. daily.	Urticaria.	Appetite and nutrition improved; gained nine pounds in weight; temperature reduced to 98° in the day and 99° at night; tubercle bacilli diminished, possibly disappeared; was able to resume her occupation.	Dr. Crandall does not think that in 30 years' experience with tuberculosis that he did as well with the "time being" treatment as with the antituberculin.
H. G. M. Kollock. .	M. 43.	Engineer.	Patient had been confined to bed for 6 months and was in the last stages of phthisis. There was a small cavity; tubercle bacilli in system.	. . . .	Eight weeks; 25 m. daily.	. . . . .	Urticaria.	Began to mend on the third day; by April 7 was able to go out, and in a short time was able to resume work; gained six pounds in weight; appetite enormous; physical signs are improved, only a small area of dulness remaining; bacilli have not disappeared; he is now able to perform his ordinary duties.	There seems to be little doubt about the beneficial effect of antituberculin upon this case.
J. C. Wilson and Dr. Kalteyer . .	M. 29.	Paper hanger; good family history.	Duration six months.	Weight 132 pounds; dry cough; scanty expectoration; night sweats; good appetite; pulse 80-100; temp. 98-100° F.; no cavities; bacilli.	Twenty-four injections.	1 to 10 c.c.	Much urticaria and swelling.	Temp. more regular, slight decrease in pulse; weight reduced to 127 pounds; physical signs became worse; bacilli.	No result.
J. C. Wilson and Dr. Kalteyer . .	M. 33.	Shoemaker; good family history; operated upon eight times for enlarged lymphatic glands.	One and one-half years.	Weight 122 pounds; loose cough, worse at night.	Twenty-five injections.	1 to 10 c.c.	Much urticaria, swelling, pain and occasional chilliness.	Conditions did not improve; patient decreased in weight.	No result.
J. C. Wilson and Dr. Kalteyer . .	M. 45	Shoe factor.	One month.	Weight 112 pounds; dry cough; some night sweats; temp. 97-103°; hectic; bad physical signs.	Twenty-seven injections.	1 to 10 c.c.	Very slight urticaria, slight chilliness and drowsiness after injections.	Temperature was more regular; lost weight; expectoration increased.	Patient became worse during the treatment.
J. C. Wilson and Dr. Kalteyer . .	M. 36.	Brewer.	Three months.	Weight 113 pounds; loose cough; much expectoration; sweats every night: high fever; hectic; 98-104 1-5° F.; bad physical signs.	Twenty injections.	Rapidly increas'd to 10 c.c	No bad symptoms.	Temperature became more irregular and hectic; pulse increased.	Patient died.
J. C. Wilson and Dr. Kalteyer .	M. 33.	Electrician.	Seven years.	Weight 113½; dry cough; night sweats; vomiting; temperature 97-100 2-5° F.; bad physical signs.	Twenty-three injections.	1 to 10 c.c.	Much urticaria; was unable to sleep.	No good followed the injections.	No result.
J. C. Wilson and Dr. Kalteyer . .	M. 23.	Leather worker.	Nine months.	Weight 123 pounds; slight cough; night sweats; temp. 97-103° F.; no cavities, but bad physical signs.	Twenty-four injections.	1 to 10 c.c.	Much urticaria and chilliness.	Patient did not improve or become worse.	No result.

Of course, one's mind naturally turned to *tuberculin* as that which was to be the means of securing the desired end, but in tuberculin the desired and necessary means did not seem to be present. Tuberculin bears in no respect the same relation to tuberculosis that diphtheria and tetanus toxins bear to their respective diseases. Tuberculin is not a toxin, and large doses injected into healthy animals fail to produce symptoms in any manner analogous to tuberculosis, or in fact, any serious symptoms at all. In all the diseases successfully combatted by antitoxins there are distinct toxins, productive, when injected into animals, of the essential symptoms of the disease.

The fact, however, that tuberculin when injected into tuberculous animals produces a marked febrile reaction and in sufficient doses, death, is one that must not be overlooked and one from which the conclusion that "antituberculin" could do good was drawn. The idea of tuberculin was not a new one. Not to go into the history of the subject, let me say that it was first investigated by Viquerat and that Paquin has written numerous papers upon the subject and claimed remarkable results from it. I could not see, when I read Paquin's papers, nor do I yet see any reasoning from which it could be inferred that *antituberculin* can be in itself curative, yet both with Paquin's and with my own antituberculin, cures seem to have been effected.

I am of the opinion that the systemic symptoms of tuberculosis and the local distribution of the bacilli are favored by tuberculin or some similar substance in the blood of the animal and the effect it exerts upon the tuberculous tissue. This opinion is in conformity with the results obtained by the injection of small doses of tuberculin into diseased animals. It is not impossible that the hectic of early cases which can not be attributed to secondary infections, may be due to the periodic reaction of the organism to tuberculin produced in its own body.

If it should be demonstrated that when tuberculin is injected into an animal it is either changed into an antituberculin or stimulates the cells of the animal to produce an antituberculin, or in any way effects the origin of an antagonistic substance or an antidotal substance, it would be quite proper to conclude that such a substance would be of benefit, when injected into tuberculous animals, by suspending those effects directly traceable to the tuberculin itself.

To determine the existence of such an antidotal substance in the blood of an immunized (or accustomed) animal is, however, attended with the greatest difficulty, for only upon tuberculous animals can the effects of tuberculin be shown, and only upon such animals can the combined effects of tuberculin and antituberculin be shown.

The method employed for the preparation of the antituberculin is too much in the ordinary path of serum therapy to need any lengthy description. The ass was the animal chosen. After preliminary examination, at the hands of the veterinarian, for good general health and freedom from glanders, the animal was subjected to a systematic series of graduated injections increasing from 1 to 150 c.c. About a month after the last injection the first bleeding was taken and upon testing was found to be free from tuberculin. The serum of the ass is unfortunately of a peculiar grayish color and is never quite clear, so that the preparation is never a satisfactory one to look at.

We have preserved the serum by the addition of 0.5 per cent. of trikresol, after which it is filtered through diatomaceous earth. In the beginning there was no theory upon which the dose could be regulated. I advised, however, that the beginning dose be 1 c.c. Soon this dose was found by the majority of the clinicians to be too large and to cause much pain in the wound, in the joints and in the back. The dosage in the reported cases varied, however, from .5 to 10 c.c. at an injection.

Supposing that the "antituberculin' was to be efficacious in the treatment of tuberculosis, what action shall we expect from it? From the premises given we may conclude:

1. If the fever be the result of tuberculin poisoning it will reduce the temperature.
2. If the rapidity of the pulse depend either upon the fever or the poison the antituberculin, by annulling the effect of the tuberculin and by relieving the fever, will slow the pulse.
3. If the spread of the disease depend in part upon the destruction of tuberculous tissue by the specific action of tuberculin and the liberation of the bacilli from it, that reaction will not take place, the tissue will not be destroyed and the bacilli will be held within bounds.
4. If the retention of the tubercle bacillus in the already diseased tissue will enable the changes in the surrounding healthy tissue to encapsulate it, and if the retention of the temperature and pulse will aid in the temporary or permanent improvement of the general condition of the patient. the antituberculin may be a means toward the production of a cure.

In what way the clinical use of the remedy thus far will bear out these theoretic considerations the accompanying analysis of cases will show.

Having thus secured a serum and a theory under which it might be a useful one, the difficulty was only met not surmounted. The proof of usefulness was yet to be demonstrated.

The first test to which the "antituberculin" was subjected was that of curing tuberculosis in guinea pigs.

1. Series 1 and 3.—Twelve guinea pigs were inoculated with tubercular sputum and then subjected to a routine of frequent subcutaneous injections of antituberculin, beginning with 0.01 c.c., and in the course of twenty-five injections, extending over a period of five months, increasing to 2.0 c.c. These guinea pigs died at varying periods from eleven (probably not from tuberculosis but from some other microörganism in the sputum) to 213 days. Excepting the first, all the animals had pronounced tuberculous lesions.

2. Series 2 and 4.—Together with these tests twelve other guinea pigs were inoculated with tuberculous sputum and subjected to no treatment. Of these one is still living, all the others died in less than 127 days.

From these experiments I felt pretty well satisfied that the antituberculin would not cure tuberculosis in guinea pigs. It next remained to see whether or not it would produce immunity to the disease in guinea pigs.

3. Series 5.—Six healthy guinea pigs were subjected to the same course of antituberculin injections as are described in experiment 1. At the end of the five months these animals all being well and strong and having gained weight regularly, were inoculated with pure cultures of the tubercle bacillus. At the present time they all show signs of tuberculosis. While small in numbers, the second experiment invited no repetition. From it I feel that we can safely conclude: 1, that the antituberculin in large doses is without injurious effect upon healthy guinea pigs; 2, that it does not immunize guinea pigs against tuberculosis.

To determine whether large doses admi [illegible] to [illegible]hy guinea pigs not previously accustomed to [illegible]

4. Series 10.—Three healthy adult

given 1 c.c. of the serum. No sympto

I suppose all medical men are now acquainted with the action of tuberculin upon tuberculous animals, to the extent that when small doses are administered a febrile reaction is manifested, and when large doses are given, death results. My last guinea pig experiments were conducted with a view to determining whether it would be possible to destroy the activity of tuberculin upon diseased (tuberculous) guinea pigs by combining the tuberculin with the antituberculin.

The fatal dose of tuberculin is quite inexact and varies with the stage of the disease, which in its turn varies with the susceptibility of the individual. The tuberculin with which I worked was of such strength that 1 c.c. of it was fatal for an average guinea pig tuberculous beyond four or six weeks. The same dose was harmless for healthy guinea pigs.

5. Series 7.—Three tuberculous guinea pigs inoculated with 1 c.c., 1.5 c.c. and 2.0 c.c., respectively, died in twenty-four hours.

Series 1.—Guinea pigs inoculated with tuberculosis Oct. 21, 1896, and injected with the serum of an immunized animal as follows:

Date.	Dose, c.c.	No. 1.	No. 2.	No. 3.	No. 4.	No. 5.	No. 6.
Oct. 27, 1896	0.01	Died April 24, 1897; 213 days.	Died; 80 days.	Died; 48 days.	Died; 65 days.	Died; 11 days.	Died; 12 days.

Feb. 10, 1897	....						
Feb. 13, 1897	....						

Series 4.—Six control guinea pigs inoculated on the same day were not frequently examined. On March 6, 1897, only one remained, which is still living, June 1, 1897.

Series 5.—Six guinea pigs in good health were subjected to the same injections as Series 1 and 3. After a long rest they were all inoculated April 7, 1897, with tuberculosis. One died May 20, 1897, another May 8, 1897. The remaining animals

Series 6.—Two healthy non-immunized guinea pigs were also inoculated with pure cultures of the tubercle bacillus on the same day. One of them died May 21, 1897, the other is still living with advanced tuberculosis.

Series 7.—Six guinea pigs were inoculated with tuberculosis Jan. 28, 1897 (sputum). In March there remained three animals of this series, all with well-developed tuberculosis. They were injected March 22, 1897, with 1, 1.5 and 2 c.c. of tuberculin. All died in twenty four hours.

Series 8.—Five guinea pigs inoculated with tuberculosis Feb. 13, 1897, survived until March 31, 1897. Each was given a fatal dose of tuberculin with respectively 0.5, 0.5 and 1.0 c.c. of the antitubercle serum. The first survived until April 15, 1897, the second until April 1, 1897, the third until April 15, 1897.

Series 9.—Six guinea pigs with advanced tuberculosis were given each a fatal dose of tuberculin and varying quantities of serum from 0.5 to 2 c.c. All died within twenty-four hours.

Series 10.—Three healthy guinea pigs each received 1 c.c. of the serum used in the above experiments; no results.

Series 11.—Three healthy guinea pigs received varying quantities of the tuberculin used above, 1 to 2 c.c.; no results.

Series 11.—Three healthy guinea pigs injected with 1 c.c. and 2 c.c. of the same tuberculin showed no symptoms.

6. Series 8.—Five guinea pigs inoculated with tuberculosis Feb. 13, 1897. Three survived until March 31, 1897, when each was given a fatal dose of tuberculin and varying quantities of antituberculin from 0.5 to 2.0 c.c. The first survived until April 15, 1897, the second until April 1, 1897, a third until April 15, 1897. In this experiment the rapidly fatal issue of the tuberculin injections seemed to be suspended as if the tuberculin had been neutralized. The outlook was now so interesting that the experiment was repeated.

7. Series 9.—Six guinea pigs with advanced tuberculosis were each given a fatal dose of tuberculin and varying quantities of the antituberculin. All were dead within twenty-four hours. This experiment seemed to destroy the results of the one before it, but the exact problem is a difficult one, for these cases may have been a little more advanced than the others, when less tuberculin would kill them; or the particular bacillus they received may have been a little more virulent, when the disease would have progressed more rapidly.

Thus far, therefore, I have been unable to prove that antituberculin neutralizes or in any way affects tuberculin in its action upon tuberculous guinea pigs. The sacrifice of my fifty or more guinea pigs seems to have been without result.

In all experiments upon animals, however, one must not forget that man is not a laboratory animal, and that he differs from them in his susceptibility. The guinea pig is an animal so susceptible to tuberculosis that it rarely if ever recovers after inoculation. Man not infrequently recovers and almost always suffers from a chronic form unknown to the guinea pig. The question now arose whether one should content himself with the results of guinea pig experiments or whether the experiment should be tried on man. Through the kindness of a number of gentlemen, I am able to lay before you results of an analysis of about twenty cases in which the remedy has been systematically applied.

I think it will be best for me to allow you to draw your own conclusions from the data given. To me it looks as if a definite improvement was obtained in some cases. A glance at the tables will show that the improvement consisted in amelioration of just those symptoms that the theoretic considerations had suggested. The temperature declined and became less hectic; the pulse slowed; the appetite and body weight increased and the cough became less violent. The disappearance of the tubercle bacilli is the most rare and least to be expected result of the use of the remedy.

It would be an egregious error not to speak of the ill effects that have been noted. I can not persuade myself that the death of the one case or the rapid decline of the two were in any manner attributable to the antituberculin which I believe to be harmless.

The most common ill is urticaria immediately following the injection, sometimes localized, sometimes general. This, I think, is due to the freshness of the serum, which was sent out almost as soon as bled.

Painful swellings at the seat of injection seem to be common and undesirable. They may be due to infection or may have some connection with the rapidity of the injection or to the character of tissue selected for the injection, or they may depend upon the freshness of the serum. They have been troublesome in many cases but have never, so far as I know, suppurated or done any damage.

Lastly, the opinion of those who have used the remedy seems to be that the dose should not exceed 1 c.c., at least for a long time. Excessive dosage seems to produce pain in the back, pain in the joints and pain in the wound.

In conclusion, I think we have in antituberculin a substance useful in the treatment of tuberculosis, in that it ameliorates certain symptoms seemingly associated with the toxic conditions present. While the exact value and action of the substance can not be proven by experiments upon guinea pigs, it seems to have been demonstrated clinically.

In closing this paper I must express my sincere thanks to Drs. J. C. Wilson and Kalteyer; Drs. James and T. Miller Tyson; Dr. H. G. M. Kollock; Dr. E. S. Reynolds and J. C. Welch; Dr. James M. Anders; Dr. M. R. Ward; Dr. Guy Hinsdale, Dr. A. A. Eshner, Drs. J. and S. Solis-Cohen, Dr. T. V. Crandall and others for their kind interest and aid in the investigation.

EIGHTEEN YEARS OF PERSONAL OBSERVATION OF TUBERCULOSIS IN ASHEVILLE, N. C.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY JOHN HEY WILLIAMS, A.M., M.D.
SURGEON-GENERAL N. C. N. G., ASHEVILLE, N. C.

In presenting this paper to your honorable body it is well to premise by stating that it is not my intention to exploit any new discovery or vaunt any new mode of treatment. I simply present deductions drawn from a personal observation of over two thousand cases, covering a period of eighteen years; during which time I have been more or less actively engaged in the general practice of medicine in Asheville, N. C., and with, perhaps, special opportunities for such observation.

My excuse for this paper is, that I believe that the profession at large has a deep interest in such observations, made by one of a fair amount of intelligence and a deep interest in his profession. It is too often true that with the specialist the "wish is father to the thought," and conclusions are reached long before the clinical facts will justify such conclusions. It is not my intention to burden this paper with futile speculations and reports of cases.

For the last thirty years or more, the plateau of western North Carolina, of which Asheville is the center, has been the Mecca toward which the faces of many of our afflicted have been turned.

Eighteen years ago I was myself an invalid, suffering from supposed pulmonary tuberculosis—I say supposed, having then no means of positive diagnosis. I was advised by such eminent authorities as Da Costa, Weir Mitchell and the lamented Pancoast that I could not live a year longer in Philadelphia and that a change of climate was necessary. My attention was drawn to western North Carolina by the writings of Hon. E. J. Aston, to whose memory I would that time and ability would permit a more fitting tribute, and the reports of Dr. J. W. Gleitsman, now of New York, who was then conducting a sanitarium for pulmonary diseases at Asheville. To his scientific observation is due much of our knowledge of the climatologic advantages of this spot. At that time Asheville boasted of but 1,700 people, thoroughly imbued with the old time southern hospitality, and pride in their beautiful country. A few months' residence there, and a more thorough knowledge of its climatic attributes, decided me that to obtain a perfect cure I should take up a more prolonged residence. I decided to remain five years at least. With passing years came confirmed health, and I have remained eighteen, with pleasure and profit. With returning health I devoted myself to the practice of medicine, but as time passed the increasing number of invalids who sought our hospitable doors caused my work to run more largely into the line of tubercular troubles. Prior to the tremendous discovery of Koch the treatment of such cases was in no manner specialized. Few if any notes were made of the treatment and progress of the cases. Systematic record of temperature, pulse and respiration was seldom made and it was not until after the discovery of the tubercle bacilli and the necessary association of their presence with the usual phenomena associated with consumption, as we now understand it, that a sharp interest was taken in such cases and the work of our confrères all over the world was closely scrutinized, and independent investigations set on foot with the hope that we might add something to our armamentarium. With greater precision in diagnosis due to improved aids and the closer attention of the profession at large, the earlier diagnosis of tuberculosis was possible.

The influence of climate in the therapy of the disease was given closer attention and its influence in the arrest and cure of the disease has been from time to time strongly set forth by all of our leading specialists, not only to the profession but to the laity as well. The influence of all this teaching is that yearly still larger numbers of primary cases are seeking the health-giving plateau of western North Carolina and western Kansas and Colorado. The ease of access—less than twenty-four hours from New York and only eighteen from the Ohio Valley, with its now well-known climatic advantages, has made this favored region the choice of most physicians of the North and East.

With a proper understanding of all that climate can do for such cases has come the full knowledge that climate is not all, and we have learned, too, that "change of climate" in part consists of a complete change in the environment of the patient, which is so large a factor in the health-restoring attributes of most of our health resorts. The freedom from business cares, household and social duties, is by no means to be underrated. Then comes, too, the change in all the nutritive surroundings of the patient; the bracing air, surcharged with ozone as shown by the meteorologic bureau, the cloudless skies and magnificent scenery, where external impressions count for so much, all conduce to an active out-door life. To such as can and will lead such a life, climate means much—those who can not and will not submit to the intelligent discretion of the painstaking physician and put off having a "good time," till the restoration of their health, had better stay at home. The result in such cases will bring discredit upon the remedy. The care and supervision of the physician whose intelligence and skill has been or should be vastly improved by the observation of the large number of cases that yearly pass in review before him, is necessary in regulating the daily details of the patient's life.

With the closer attention that has of late years been given to the prodromic signs of latent tuberculosis comes an earlier removal from the environment of the patient with corresponding benefit.

In speaking of latent tuberculosis, I have had impressed on me the influence of heredity and a careful study of over 70 per cent. of my patients shows the hereditary taint. In this connection comes the thought of prophylaxis. I would strongly urge the propriety and even necessity of the family physician making regular and stated examinations of every member of the families who may be intrusted to his care, in whom there is even a remote suspicion of the hereditary taint. The importance of the early recognition of tuberculosis is being daily urged upon us—so much can be done in the earlier stages and so little in the later. Cases in the later stages of the disease, with large suppurative cavities, septic chills and fevers, amyloid degeneration of the kidneys, tubercular infection of the intestinal tract with diarrhea—any or all of these I have seen on their arrival in Asheville and have had to advise their immediate return—can have the pathway to the tomb made much smoother with the comforts of home.

The various treatments that have been exploited by their fond discoverers have all passed in kaleidoscopic review, Bergeon, superheated air, etc. Of the most of them it is unnecessary to speak. I have had an opportunity to observe all of them as well as to experiment with the various remedies that have found favor with the profession.

The grave disturbances of nutrition in all cases of tuberculosis, whether it be primary or secondary, is a matter of deep interest. It is a recognised fact that only through suitable changes in all the nutritive processes and surroundings of the patient can we hope to deal successfully with the profound cachexia of tuberculosis in any form.

Possessing no known specific, we have been led to experiment with any and all remedies, foods and physical surroundings that contribute in any way to the building up of the physical and vital forces. The gamut has been run in the way of chemic foods—so-called—but we have to admit that the chemic laboratory has not as yet furnished us with anything that can supplant nature in the catabolic and metabolic processes necessary to a stable equilibrium in the physical economy. Anything that will assist nature to resume a wholesome and healthy function of digestion and assimilation will prove to be a valuable addition to our armamentarium.

Intestinal antisepsis—thorough and complete as may be—appears to have first place in conducing to the nutrition of the patient. In this class of remedies creosote appears to have first rank. I have observed no special benefit from the inordinately large doses given by some. I have given it in doses of from 20 to 90 minims daily, but have decided that I get as good results from the smaller as from the larger doses.

Next to creosote, and I am sometimes of the opinion that it should come first, is the internal administration of ichthyol. I have used the remedy for the past eight years in daily doses of from 20 to 100 minims, and my case books show a very material modification of the symptoms in a large percentage of cases, especially marked in the earlier stages. Glandular cases and those showing evidence of gastric and duodenal catarrh come especially within the range of of its power. Since reading the remarkable results obtained by Scarpa I have had my faith in its powers much strengthened. In no one case have I noticed any unfavorable result from its usage, except an occasional bronzing of the skin, coming on about the third or fourth week of its exhibition and lasting a week or two. In a large percentage of the cases in which I have used it I have noticed a gradual involution and degeneration of the bacilli, with a reduction in number, and their final disappearance. The assimilation is improved and the patient takes on flesh; the character of the sputum is changed in a marked manner, loosing its heavy, viscid, nummular character and becoming thinner, with greater ease in expectoration. There is an improvement in the appetite and digestion with recession of the daily temperature and lessened night sweats.

The use of the pneumatic cabinet with forced inhalation of the vapors of creosote, oil of pine needles, oil of cedar and the various balsamic preparations finds great favor. The stimulation of the local circulation gives consequent freer oxygenation of the blood. The expansion of the bronchioles and vesicles helps to free them from retained mucus and gives a larger breathing capacity, and it counteracts the contraction of connective tissue from inflammatory deposits.

I think it is the general consensus of medical opinion that so-called intra-pulmonary medication, whether by sprays, vapor or steam baths, is, *per se*, of but little avail and that our best efforts should be directed to the restoration of the impaired nutrition and the stimulation of the leucocytes and phagocytes of the blood. If the theory of Metchnikoff be true, and it has not yet been discredited, the remedies that will stimulate this vital action will prove of best service to us.

In this connection I will mention my personal use of Koch lymph and later of the modified product of Klebs known as Antiphthisin.

I was an early user of Koch's tuberculin and was, as were most of us, enthusiastic over the promises of the future. Unfortunate results in some of my earlier cases, however, produced such revulsion of feeling that for months the remedy was allowed to fall into innocuous desuetude. More careful study, however, of the physiologic action of the remedy, with more favorable reports from observers at other points, induced me to give it further trial with careful precaution as to the initial dosage and thorough espionage of the patient for several hours after its administration. With care in its usage, I secured in a few cases some remarkably favorable results, but in the majority of cases confess to disappointment.

The advent of the serum therapy gave renewed interest in the investigations of Koch and Klebs The modification of the remedy as proposed under the name of antiphthisin or purified tuberculin seemed to offer a safer remedy than the earlier product of Koch's laboratory and to admit of a more extended application. It has been, I think, proven by clinical observation and experience that in the earlier or prodromic stages the antiphthisin Klebs or the later product of Koch's laboratory may give almost marvelous results. My case books show that within the last two years I have had not less than thirty absolute and unequivocal recoveries under the administration of this remedy alone.

It is not within the province of this paper to discuss the physiologic action of this remedy. I am simply noting clinical results. I may, however, mention that I do not think that antiphthisin possesses any bactericidal power as does the antitoxin of diphtheria but that it does produce in the body of the patient, by some catalytic power acting as a special ferment upon the healthy tissues of the body, that stimulation of phagocytosis that enables the patient to deal with the bacilli, producing if you please a personal antitoxin. With such specific treatment of the patient comes the general care of all the functions of the body. Septic chills and fevers are not to be controlled by quinin or the coal-tar products. The usage of these latter remedies has been generally discarded. The relaxed skin renders the patient more susceptible to the effect of the diurnal changes common to all elevated latitudes. The daily rise of temperature is best combated with perfect rest in bed with liquid food. With extreme temperature, I have gotten the best results from the use of the ice-bag over the precordium or cold packs to the chest. Oil of turpentine with subgallate of bismuth appears to give the best results in diarrheic cases—opiates are seldom required, save possibly in the form of codein to control cough. The large diurnal range of the thermometer renders the wearing of woolen or silk or other non-conducting material next to the skin imperative. The powerful and stimulating effect of a strychnia nitrate upon the vascular and respiratory centers makes it a valuable adjunct.

Hematic remedies, especially Gude's pepto-mangan, gives excellent results, epescially in cases of an anemic character and in those of a mixed infection. My experience in the Shurly-Gibbs treatment in sixty-four cases has been unsatisfactory in every respect. The Edson aseptolin has proven to be of service in about 14 per cent. of those cases that came to me with a history of malarial infection.

The ingestion of as large quantities of nitrogenous foods as can comfortably be taken care of by the digestive organs, the out-door life, the careful conservation of all the forces of the body will add much to that uncertain factor known as climate. In the selection of cases suitable for transfer to the plateau of western North Carolina I have a few words of caution to offer. Examine your cases carefully with all the aids that modern research has given us. A microscopic examination of the sputum will be of invaluable aid. Cases of mixed infection of the mesentery and the great eliminative organs are by far better off at home. The familiar surroundings, the faith and hope inspired by the old and trusted family physician, the thousand nameless comforts of home will prolong a possibly useful life that would succumb certainly and speedily under the depressing influence of absence from home and friends. Nostalgia is as important a factor in these as with our sick and wounded in the late war.

I have noticed but little effect upon the nervous system from our medium altitude, except that in most cases it has a distinctly soothing effect and that our visitors sleep better here than at home. Cases of a hemoptistic character are usually advised to try the lower altitudes of the eastern and southern slope of the Blue Ridge and I think that Tryon, in the western extremity of the famous Thermal Belt, is the ideal spot.

The financial condition of the patient should also be carefully considered, since to get the best results from climatic influences he should be provided with not only the necessaries but even the comforts and luxuries of life. Very little benefit can be obtained from such climate as can be obtained from a little back room in some second- or third-class boarding house. Let him keep away from the clubs and hotel lobbies and abstain from all the frivolities that are found in all well-known resorts. Do not advise him that the climate will do all for him that is necessary. Advise him by all means to consult on his arrival one who is familiar with all the various things that will conduce to his well being and capable of advising against the dangers that may result from a total change in his habits and surroundings. You will find more than one physician at all such resorts and it is presumable that they are as honest as the general run of the profession.

I would sugggest that you submit your observation of the patient, with history of prior treatment to the physician to whom you may intrust him, noting the remedies which you have found of special benefit, and any peculiarity of temperament or habit with which you may be acquainted. Above all be honest with your patient. It is not kindness to tell him that he has a little bronchial trouble, just a little catarrh or something of that sort, and that a few days' sojourn in a pleasant climate will set him all right. Tell him why you send him and the necessity of devoting all his time and energy to getting well. Tell him the truth.

53 Haywood Street.

DR. DeLANCEY ROCHESTER'S "REPORT ON THE TREATMENT OF PULMONARY TUBERCULOSIS."—REPLY.

BY PAUL PAQUIN, M.D.

ST. LOUIS, MO.

Under the above caption appears in the Journal of the American Medical Association, July 10, 1897, the report of Dr. DeLancey Rochester of Buffalo, N. Y., as presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1–4, 1897. This report I had the pleasure of hearing and was disappointed in not being able to discuss it, owing to the numerous other papers on tuberculosis presented before that and other Sections of the Association, and for the discussion of which only five minutes were granted to each member.

The report of Dr. Rochester seems to be a comparative statement of the results he obtained in the use of Edson's aseptolin, Paquin's tubercle antitoxin and Vaughan's nuclein. I have read it carefully and am compelled to reply because of the manifest injustice it does the cause of sero-therapy and myself. In order to present my case properly before the readers of the Journal and the members of the American Medical Association, it is necessary for me to give a history of Dr. Rochester's tests of "Paquin's" serum, and for this purpose I will be obliged, much to my regret, to quote from his letters to me and from mine to him. I feel justified in doing this because Dr. Rochester in his conclusions, gained from such a meager experience, declares against Paquin's tubercle antitoxin in unmeasured terms, and because the language and tone throughout the report is one to discourage the profession from using serum, and to belittle the method of treatment, to class it with aseptolin, and to exalt, beyond reason, another therapeutic agent. Dr. Rochester's grounds are not tenable.

On Nov. 28, 1896, Dr. Rochester addressed the laboratories bearing my name and made this statement: "I should like to compare Paquin's with Maragliano's serum." To this I replied, under date of Nov. 30, 1896, and made the following statement: " . . If you have more than a half dozen cases on hand at one time that you will treat for three months, or until the disease shall have disappeared, or until the patient shall have proven refractory to this method of treatment, we will make you the hospital reduction of 25 per cent., on condition that you will make careful examinations, charts and reports, as per enclosed blank,[1] you keeping a duplicate to assure yourself that we will not take advantage of anything favorable you may say and leave other results out. Furthermore, we would exact a microscopic examination of the sputum, not only with reference to the bacilli of tuberculosis, but also with reference to all pus germs, their kind and number; whether cavities exist or not, and the nature and degree of fever. You will understand that it is only on the grounds of a thorough diagnosis that sero-therapy can be intelligently applied in tuberculosis, and numerous reports have come to us of failures simply because the serum *was applied in absolutely hopeless cases*, or that a serum designed exclusively to act against the bacilli of tuberculosis *was used in cases of mixed infection* when a combined preparation against mixed infection should have been used. Any communication you may send me personally will be answered with pleasure, etc."

On Dec. 2, 1896, Dr. Rochester wrote me a long and pleasant letter, in which he makes this statement: "*I have none* (meaning no patients) in what may be truly called the incipient stages." In this letter Dr. Rochester also *objects* to sending the chart of his diagnosis, on blanks sent him by me, as mentioned above. To this letter of his I replied on December 4, and made the following statement: "My object in asking you to file your diagnosis and record with me is not for the purpose of publishing the same in our literature without your consent, but it is for my own guidance in experimentation, clinical work, and in our efforts to improve the serum. You will note by my previous letter that I mentioned the fact that some cases of mixed infection should be treated with serum *purposely prepared*, having for its object *the arrest* of the *various complicating germs* as well as the bacilli of tuberculosis. This is one of the reasons why we are so anxious to get the results of the microscopic analysis and a proper diagnosis, that we may supply the proper serum.

"In your cases you have a splendid opportunity of doing some good scientific work and I would respectfully suggest that you institute your work in such a way that you may be able to determine the results by the use of *pure* anti-tubercle serum and the *mixed* anti-tubercle and anti-streptococcus serum in pure and mixed cases of tubercular infection. For that purpose, I think the following mode would be practicable: I would first treat every patient with pure anti-tubercule serum, for several weeks, say a month or two, and note the results carefully. In all cases in which there is no imprvement, and in which mixed infection was discovered, I would then use the serum for mixed infection, which we would supply on demand, and note the result. By that means you could make a comparative report. You may, however, think best to start your work on a different basis, and that of course, is for you to decide.

"I thank you very much for your kind reference to my work in lecturing to your classes, but I beg to *warn the profession against too sanguine hopes in the use of serum in tuberculosis*, unless used in such cases where disintegration *has not advanced beyond repair*. It is true, we have on our list of recoveries, cases that seemed absolutely hopeless that had been given up by physicians of reputation and without question very competent, but these are exceptions and nothing should be left undone, in private practice at least, to sustain the action of serum by other methods. The digestive apparatus particularly needs careful attention and so does the nervous system.

"With reference to the business portion of our relations, I would beg you to correspond with the laboratories, as per enclosed card. Anything purely professional I will attend to with great pleasure, etc."

January 16, 1897, I received a note from Dr. Rochester saying that his patients had not done well but that he was "convinced he was working in the right direction." This I answered January 18, and made the following statement: "It is true that sometimes in desperate cases, sero-therapy succeeds in producing quite an improvement, and I have in my charge now patients in whom cavities seem to have dried up. But in a general sense one *need not expect much in advanced cases* of tuberculosis.

"On the other hand, it is well to consider that in almost every case of mixed infection it is the growth and products of the complicating germs that cause the great injury and eventually death. Chills and high fever, I am sure, are almost wholly due to these factors, and in such cases a serum prepared especially to meet these conditions is necessary. In all cases in which I find profuse quantities of mixed germs, besides the bacilli of tuberculosis, particularly when there is fever above 101, 101.5 or 102, and still more particularly when there occur rigors, and the expectoration is more or less profuse, I use a serum produced by the immunization of animals with the germs that complicate tuberculosis. I also in some instances mix the two serums, but in any event, the serum should be prepared according to the case. I have not yet put this serum on the market, but have been experimenting with it for some time and the results have been more gratifying than with the pure anti-tubercle serum, so that I would suggest that you make charts of your cases with reference to mixed infection and submit them to us, and from this I may be able to give you a serum that will prove more satisfactory.

"Further, I wish you to consider that tuberculous patients with *hereditary influences* are poor subjects for sero-therapy alone, seemingly because their general constitution, particularly the nervous system and digestion are very deficient, and the neutralization of the toxic products of the bacillus of tuberculosis and other germs is not followed by the arrest of the germs themselves and their growth, to a sufficient degree.

"I trust that you will give the serum *a fair trial* in all its forms, and I will be very glad to coöperate with you if you will permit me. I am anxious, in any event, *to know the nature of your cases*, and I think *it but fair* that you should kindly file with me a charted diagnosis of each, history, etc., on the blanks furnished you for that purpose. *My object in this is to guard against unjust criticism*, which I do not anticipate from you, but I think it fair that I should be prepared at any turn. Another object is to keep track of the cases the serum is used in by thinking men, to the end of advancing sero-therapy, in tuberculosis particularly. I believe that I begged you to send me these charts before."

---

[1] This blank chart contains, on one side, cuts of the chest, back and front, and diagrams on which to note the nature and location of the physical signs and lesions; on the other side, blank form to write the history of the case, existing conditions, microscopic analysis, uranalysis, diagnosis, prognosis, etc.

February 13, Dr. Rochester wrote: "I have become convinced that the cases that present themselves at the County Hospital are *too far advanced for good results*, so have discontinued serum." In the same letter he says: "I was struck by *the fairness of your statements* at Baltimore and disgusted with the *unfair criticism* of a man from ———." I had been led to believe that with such feelings, Dr. Rochester could not himself be unfair.

I have other letters from both parties, from which I might quote to demonstate the absolutely legitimate and careful grounds on which I was attempting, through Dr. Rochester and at his request, as I have attempted with the assistance of many others whom I trusted, to improve sero-therapy in tuberculosis, at the same time taking step to protect myself and the work I was doing. It will be noticed from my letters to Dr. Rochester, that I specified repeatedly that little good could be expected from advanced cases of tuberculosis, and he himself acknowledged that the patients he had in hand were too far advanced, yet this is the very class of cases he chose in his attempts to demonstrate that Paquin's serum was painful and useless. Not only was the Doctor warned by letter, but the directions which accompany each bottle, and the literature on the subject from a number of physicians, all in good standing and splendidly equipped, demonstrate how the serum can be used with little or no pain, and the class of patients in which this method of treatment can be beneficial. He was advised that cases with cavities and other advanced conditions need not be considered favorable for serum treatment, and none of our reports claim more than a couple of cases of laryngeal tuberculosis (in which he deprecates serum) which were benefited materially.

Aside from these circumstances, I deem it unjust on the part of Dr. Rochester, to make a report comparing Paquin's serum with Edson's aseptolin rather than with Maragliano's serum, as he informed me he intended to do and for which purpose I sent the serum. I never knew he intended to compare sero-therapy with that justly discredited vagary known as aseptolin. I deem it unfair too that he should have chosen cases in which I claim little for serum, to minimize Paquin's serum.

I beg now to refer you to the cases he reports, as published in the JOURNAL, pages 69. 70 and 71, issue of July 10.

The first case in which he used serum had been on aseptolin from May 4 to December 1, 1896—seven months. Following are the chief points of diagnosis before beginning aseptolin: Case 1, D. M. (page 69 of the JOURNAL), "coughing and raising considerable . . . irregular chills followed by high fever and night sweats; . . . tubercular infiltration of right upper lobe." There was no cavity then. The Doctor claims that the patient improved and yet on December 12, when he began Paquin's serum (see page 70. first case) he declares that the following condition existed: "Infiltration in upper left; *cavity in upper right*." Thus a cavity had formed in the course of the seven months of breaking down during the aseptolin treatment. And yet, the Doctor used this case to make a comparative record of results between aesptolin, serum and nuclein. Was this scientific or reasonable or fair?

The second case, F. S., had also been experimented with. Aseptolin has been injected *six months* in this patient before beginning serum. The diagnosis' notes, May 4, 1896, before beginning aseptolin, (page 69 of the JOURNAL) give the following: "For six months the patient had gradually failed in health and strength: there was anorexia, anemia, marked cough, profuse expectoration, afternoon fever and profuse night sweats. Tubercular infiltration of upper and middle lobes of right lung." Now, on November 8, after the six months of aseptolin treatment Dr. Rochester declares that "there is infiltration of *entire* right lung, and *cavity* in left upper lobe surrounded by zone of breaking down lung; aseptolin stopped." The case had gotten much worse. December 14, just before beginning serum, this same aseptolin case was re-examined by Dr. Rochester and he describes his physical condition as follows: "Infiltration of left apex and of right upper, with bronchitis in right middle lobe." Mark that he no longer mentions the cavity, and thus the case appears milder to the readers. Is this scientific, fair or reasonable?

Case 3, of the serum series (p. 70, JOURNAL), is case four of the aseptolin series (p. 69). Before using aseptolin in him (for six months) he says, May 2, 1896, the patient is "anemic, has no appetite, feels very weak, suffers from dyspnea. There is evidence of consolidation of upper left lobe and scattered areas of broncho-pneumonia through rest of left lung, and slight bronchitis in upper right. Coughs a great deal, etc." Nothing is said in this diagnosis of a cavity existing. In fact, the very day the aseptolin was stopped, December 8, Dr. Rochester explains that there "was no change in patient's condition." And yet six days later before beginning serum he says: "There is an infiltration in the upper left and in the middle right and a cavity in the upper right." This undoubtedly is an acknowledgment that the patient has been going down hill with aseptolin, and still he considers it a patient to test serum. Is this reliable work?

Case 4 he describes as being with a *previous history*. infiltration of left upper lobe as far down as the level of the second rib in front, and as far as the spine of the scapula behind. "Considerable cough and expectoration."

Case 5 he describes as having *a previous history;* pneumonia five years ago; cough for two years; night sweats; cough and expectoration considerable; sputum often tinged with blood; scattered areas of broncho-pneumonia in both lungs, together with considerable emphysema; cavity in upper right lobe."

In the above descriptions there exists much discrepancy between the diagnosis made in identical cases, for the use of aseptolin and that for the use of serum and there is ample evidence to give the opinion that every one was advanced beyond permanent improvement, whether treated by nuclein, protonuclein or anything else devised by the human mind. They constitute the very class of patients against which I had warned Dr. Rochester not to use the serum with any hope of even satisfactory temporary results, as can be seen by the foregoing evidence: consequently, Dr. Rochester was not warranted or justified in taking the radical position he did against sero-therapy in tuberculosis, in an experience with five cases, none of which he treated longer than one month, and four of which were moribunds, and it is unjust if not absurd, to compare sero-therapy with aseptolin. Another case, glandular tuberculosis, not mentioned above, he treated longer, and that one he himself says was improved.

As to nuclein I know it is of value in its proper sphere; but I wish to say a word concerning Dr. Rochester's tests with this preparation also, to which he ascribes invariably good results. Let us see how he dealt with the patients under nuclein:

Case 1, Miss C. (page 72 of Journal), it seems is mentioned only to reflect on serum, for there is no scientific or practical data whatever with the mention of it, and there is a reiteration of regret to have used serum in her. (Perhaps this is Miss B., page 71. Inaccuracy throughout the report makes many points hardly intelligible.) The case *had not been tampered* with at all with aseptolin before nuclein was tried.

Case 2, Mrs. W. F. H., June 25, "infiltration with some softening of upper lobe of left lung," later "infiltration of the upper right lobe and entire left lung with softening of the upper lobe"; no cavity then. Nuclein was used for *two years*, and May 20, 1897, Dr. Rochester found "a *cavity* in upper left with infiltration about it." That is not such a wonderful cure. Probably nothing known to the human mind can arrest the disease in this case.

Case 3, Elizabeth McD., Nov. 11, 1895, "infiltration upper left, cavity surrounded by softening in upper right, etc." Nuclein used from November, 1895 to Aug. 15, 1896, "when she passed from under observation, still coughing occasionally and with some condensation in right apex." It does not appear that Dr. Rochester saw this patient after Aug. 15, 1896, when she still exhibited the latter symptoms, and yet in May, 1897, he hopefully remarks, "this case I consider *recovered* though there remains slight condensation in upper right." Is there a physician justified to call such a case a recovery?

Case 4, John D., Nov. 14, 1895, "infiltration in upper right; infiltration and slight softening in upper left; bronchitis in lower left." Nuclein was used till May 20, nearly seven months, and then Dr. Rochester found a "cavity." This was not present at the beginning of treatment. And "the sputum still contains the tubercle bacilli." There is not very great evidence in this case in favor of nuclein in advanced conditions.

Case 5 gives much better encouragement.

Case 6, David D., which had done so badly under serum on account of pains, etc., seemed to be naturally refractory to hypodermic medication, for he was prostrated repeatedly after injections of nuclein, and the fear of this, said Dr. Rochester, is what precluded (?) good results.

Case 7 was treated only two weeks, entirely too short a time for any improvement to have much significance, though the results are highly encouraging.

I have used nuclein extensively by hypodermic injections and I know that it does produce pain very frequently, and I have known physicians who hesitate about its use, just as Dr. Rochester did with serum on the plea that it produced too much pain, and the plea is just as unwarranted as it is in serum. If properly used in proper cases this criticism is without foundation either in serum or nuclein, except in a few refractory and sensitive patients with respect to hypodermic medication in general.

While the above cases are described sufficiently by Dr. Rochester to warrant any physician in declaring 98 per cent. of them hopeless under any kind of treatment, no one can tell to which class they belong. We have at least the following classes: Destructive broncho-pneumonia and cavities; destructive broncho-pneumonia without recognizable cavities; with diffuse febrile pneumonia, with or without a destructive character; with diffuse non-febrile broncho-pneumonia, with or without destructive process; with circumscribed febrile broncho-pneumonia; with circumscribed apyretic broncho-pneumonia. Information should have been given us on this question if it was intended by the author to show cause for success or failure. To take such a radical stand as he did one should have positive evidence.

As to the pain the Doctor says serum induces, I have already alluded to it. But I wish to say further that the directions accompanying each bottle of serum mention every untoward symptom of sero-therapy, and it is not long before most physicians who use serum find the means, if they follow the directions, of preventing pain and all other possible untoward effects of hypodermic medication. This pain is rarely worth mentioning and is caused by the preservative, which in one form or another, is found in all antitoxins and other organic products including nuclein. Pain is not a special result of Paquin's serum, as it seems is the author's intention to show. Dr. Rochester's experience on this score should not be utilized as a factor against the use of serum.

In refutation of Dr. Rochester's claim of serum uselessness, which is based on a few week's experience with five unavoidably fatal cases, four of which were practically moribunds before he began, I beg to mention the following physicians who used serum and are still using it when proper cases offer, not to mention the reports which I have myself made.

Dr. L. L. Shropshire, San Antonio, Texas, five cases of recoveries and improvements. (Reprint from *New York Medical Journal*, January, 1896.)

Dr. J. R. Lemen, Marion Sims' College, St. Louis, Mo., two cases recovered. (Reprint *New York Medical Journal*, Sept. 1, 1895).

Dr. J. A. Dunwody, Cripple Creek, Col., four recoveries and improvements. (Reprint New York *Medical Record*, July 11, 1896.)

Dr. H. C. Mitchell, Carbondale, Ill., two cases recoveries and improvements. (Reprint *North American Practitioner*; presented to the Southern Illinois Medical Society, Nov. 15, 1895.)

Dr. Hoell Tyler, Mentone, Cal., five cases recoveries and improvements. (Reprint *Southern California Practitioner*, October, 1896.)

Dr. William Miller, Boerne, Texas, one case recovered. (Reprint from *Southern California Practitioner.*)

Dr. J. M. Allen, Professor of the Principles and Practice of Medicine University Medical College, Kansas City, Mo., gives four cases, recoveries and improvements. (Reprint Journal of American Medical Association, May 29, 1897.)

Dr. F. T. Chamberlain, physician nose, throat and chest, East Hospital, Washington, D. C., under the use of various serums including Paquin's, reported twelve cases of decided improvement. (Reprint from *Virginia Medical Monthly.*)

Dr. Landon B. Edwards, ex-President Richmond Academy reported decided improvements and of Medicine and Science, splendid benefits from the use of serum. recoveries and (Reprint *Virginia Medical Semi-Monthly*, 1896.)

Dr. William Hutson Brioleau, Summerville, S. C., four recoveries and improvements. (Reprint *New York Medical Journal*, June 26, 1897.)

Dr. J. G. McFarland, Professor Pathology University of Pennsylvania, Philadelphia, June 3, before the American Medical Association. (New York *Medical Record*, July 10, 1897.)

Dr. J. D. Dillin, Ft. Worth, Texas, reported the cure of his wife.

At least twelve new reports testifying to the efficacy of Paquin's serum, from as many physicians of competence, are awaiting the medical press for publication.

I could mention the names of at least a hundred or more physicians, who have used serum according to direction, and obtained equally as good results, but they have not as yet reported to the profession and I have not time to get permission to quote them. The above-mentioned are some of those who *have* reported to the medical press and their statements can be veriged by any one who will read their papers.

Now I will admit, as I did to Dr. Rochester before sending his serum for the treatment of his patients and warning him against too great expectation in advanced cases, that pure anti-tubercle serum is *not sufficient* in advanced cases, for in them there is *always* mixed infection. The Doctor did not heed me in this, nor did he when I explained that he should use a serum purposely prepared, for all mixed infections, and at least four of his cases were unavoidably mixed. The one single case which he claims was pure tuberculosis(?) was not sufficient evidence to determine anything, especially as defective circulation about the diseased areas in laryngeal tuberculosis adds seriously to the difficulty of treatment. He confesses he knew better in saying (paragraph 4, p. 71) "good results from a specific antitoxin should not be looked for in such cases." Yet he deliberately and in defiance of advice sought by him, and given to him, took moribund cases, used serum least suited to them and draws a parallel with an exploded nostrum on one side and worthy nuclein on the other, giving months of trial to aseptolin, years to nuclein and only a few weeks to Paquin serum, chiefly in aseptolin-wrecked constitutions.

I regret to have to take the matter up in this form, but since Dr. Rochester has not hesitated in the use of unwarranted language, based on insufficient data, after I had taken the pains to warn him against the use of serum in the very cases which he used to form his rash opinion; when I find the whole report so full of inaccuracies and discrepancies; and when I trusted him to do really scientific work, as a man, physician and scientist, I feel warranted in my action both for self-protection and in behalf of the cause of serotherapy. I trust that Dr. Rochester will do me justice.

MY EXPERIENCE WITH PAQUIN'S ANTI-TUBERCLE SERUM.

BY S. LANE ANDERSON, M.D.

CHADD'S FORD, PA.

I have used Paquin's antitubercle serum on several cases, and for me it has done all that is claimed for it.

Case 1.—Miss G., aged 25, weight 130 pounds. January and February, 1896, suffered from an attack of la grippe; did not clear up properly. Symptoms three months later, in May, dull and pneumonic areas in right lung amounting to pectoriloquy; acute lancinating pain, purulent expectoration, continuous cough, and exaggerated and very *painful tubercular pharyngitis*, daily afternoon rise of temperature, excessive night sweats and most offensive diarrhea; had also two hemorrhages in June. My treatment up to this time had been the recognized standard remedies for the existing conditions. A professor of laryngology from one of our colleges in Philadelphia had seen the case and his suggestions had been faithfully carried out, with absolutely no amelioration of the trouble. Two consultants pronounced the trouble advanced tuberculosis. In July, 1896, weight had fallen to 116 pounds; had had no appetite for weeks, in fact, had not averaged four ounces of food daily. Commenced using serum in July, 5 m.. at first, increasing 3 or 5 m. daily till 30 m. was the regular dose.

Result.—In less than one week the throat was decidedly better, the sputum lost its pus character, night sweats lessened, cough was much improved; appetite became ravenous, could eat diet she previously had no taste for. In fourteen weeks, after using five bottles of serum, she returned to work (clerking in store) weighing 126 pounds, feeling well; throat entirely well, good appetite, sleeps well, and I might say, 100 per cent. better in every way.

I used in all on this case eight bottles of serum. Never had an unpleasant experience, and toward the last only gave her 25 m. every other day. She complained of tasting it in her throat within five minutes after the injection, and if any pain existed before the injection it would relieve it almost immediately. As I am very skeptical I used the serum believing the result would be negative, as I did not think Miss G. would live till September.

I have used it on other cases and the result has been on a par with this case, and I will also add that I shall continue to use the serum on any and all cases that will submit to it. I have never failed to see the benefit in seventy-two hours. It gives relief from those distressing symptoms which render that class of sufferers so miserable. All cases in which I have used it, after three or four weeks, I put on the following:

℞	Syrup hypophosphites, comp. (Fellows)	℥ ij	64 00
	Spirit. frumenti Ol. morrhuæ	āā ℥ iv	128 00
	Extract malt, q. s. ad	℥ xvj	512 00
	M. Sig.—ʒ iv in H_2O fifteen minutes before meals.		
℞	Quinin sulph.	ʒ ij	8 00
	Ferri sulph. exic	ʒ j	4 00
	Strych. sulph Acid arsenious	āā gr. iij	19
	M. Ft. pil., No. lx		
	Sig.—One after meals.		

These formulæ I have always found well borne after two or three weeks use of the serum, no matter how rebellious a stomach may have been prior to that time. My patients do well on this treatment and have never yet had to discontinue it. I am treating what was said to be a hopeless case now and she is doing well.

REPORT OF OBSERVATIONS MADE UPON A CASE OF GASTROSTOMY.

BY M. F. COOMES, A. M., M. D.

Professor of Physiology, Ophthalmology, Otology and Laryngology, in the Kentucky School of Medicine; Member of the American Medical Association, and the Kentucky State Medical Society; Ophthalmic Surgeon to the Louisville City Hospital and the Kentucky School of Medicine Hospital: Consulting Ophthalmic Surgeon to St. Mary's and St. Elizabeth's Hospital, etc.

LOUISVILLE, KY.

The stricture of this child's esophagus was the result of swallowing concentrated lye nearly a year before he was operated upon.

At the time of the operation Feb. 16, 1896, the stricture was impervious, not admitting the smallest bougie, and the child had not swallowed for six days. A modified Franck's operation was performed, and a rapid and uninterrupted recovery followed. The patient was five years of age.

Some six weeks after the operation he began swallowing fluids, and is now able to swallow thick broths and take milk with mush or oatmeal, which shows that the cicatricial tissue is being rapidly absorbed. Observations with a view of determining the quantity and quality of fluid found in the stomach, were commenced on Oct. 10, 1896, at 12:45 P.M., and were made on the various dates given below in connection with the tests. The greatest length of time between the periods of removal from the stomach and the time at which the digestive tests of the fluid were made, was 271 days, and the shortest 131 days.

All of the specimens were passed through ordinary filtering paper as soon as they were drawn from the stomach; after filtering, the tests for hydrochloric and lactic acid were made. The fluid was then placed in a clean bottle and properly numbered and labeled so that no mistake as to quantity, date or chemic reaction could be made. All of the specimens have been kept in a steam-heated room where the average temperature was 70 degrees, F., and on many occasions a much higher temperature was obtained, but it never went below 50 degrees, F. There was no special effort made to exclude the air from any of these bottles, as their mouths were only stopped with corks or cotton wool. All of the specimens seem to be well preserved at this writing, with one exception, and that is the specimen which was obtained on Oct. 15, 1896, at 8:30 A.M., after fasting 12 hours. On the top of this fluid is a moldy mass, the greater portion of it being white, a small fringe around the edge being decidedly black; this specimen showed less evidence of lactic acid than any of the others.

I did not see him from October 16, until October 26. On that day he came to town in an open wagon with his parents, who live fifteen miles in the country. He had breakfasted at 6 A.M.. partaking of some sweetened coffee well mixed with a goodly portion of rich cream, and some oatmeal mush. This youngster is no exception to the rule which governs the *genus homo.* He loves to gratify his appetite and persists in swallowing those things that are pleasing to his palate, as sweets and certain kinds of soups. If it is an ordinary broth or something which he *does not fancy, he* prefers to have it put into the stomach through the opening which is in that organ, rather than go to the trouble of swallowing. *He arrived at my office at* 11 A.M. Early in the morning the father had purchased him some peppermint candy with red stripes on it. He continued to suck the candy and swallow the saliva for a greater part of the trip, but had nothing else to eat or drink from 6 A.M., until he arrived at my office. I removed from his stomach, at that time, 150 cubic centimeters of gastric juice. It was decidedly pinkish in color, the color being due to the pigment upon the candy. There was also a decided odor of peppermint in the fluid. Both hydrochloric and lactic acid were present. No digestive test was made.

The results of the tests reported to determine the digestive powers of the different specimens of gastric juice, were made on July 9, 1897, 271 days after removal from the stomach. It will be noted that No. 8 was procured on Feb. 27, 1897, or 131 days after removal from the stomach, and that there was no digestive test made of No. 1.

No. 1.—October 10, 1896, at 12:45 P.M., after fasting five hours, 19 cubic centimeters of gastric juice were removed from his stomach. Tests showed both lactic and hydrochloric acid present.

No. 2.—October 13, 1896, at 8 A.M., after fasting twelve hours, 10 cubic centimeters of gastric juice were removed and both acids found present. July 9, 1897, this fluid completely digested boiled egg albumin and readily coagulated milk, demonstrating its active properties.

No. 3—October 13, 1896, at 1:30 P.M., after fasting five hours, 45 cubic centimeters of gastric juice were removed. Both acids were found present. July 9, 1897, this specimen possessed all the qualities of normal gastric juice, readily digesting boiled egg albumin, and coagulating milk.

No. 4.—October 14, 1896, at 8:30 A.M., after fasting thirteen and a half hours. 12 cubic centimeters of gastric juice were removed. Both acids were present. July 9, 1897, this specimen was not very active in digesting albumin, but promptly coagulated milk. The coagulum was solid and not flocculent like that produced by gastric juice under ordinary circumstances.

No. 5.—October 14, 1896, at 2 P.M, 65 cubic centimeters of gastric juice were removed. He had been fasting five hours and forty-five minutes. Both acids were present. July 9, 1897, this specimen gives no reaction whatever upon albumin or milk; that is, it will not dissolve albumin, nor does it coagulate milk; showing that it has undergone complete degeneration, possessing none of the properties of a digestive fluid.

No. 6.—October 15, 1896, at 8:30 A.M., 45 cubic centimeters of gastric juice were removed. He had been fasting twelve hours. Both acids were present, however only a trace of the lactic. July 9, 1897, this specimen possessed comparatively active powers in digesting albumin and coagulating milk.

No. 7.—October 16, 1896, at 3 P.M., 20 cubic centimeters of gastric juice were removed. He had been fasting five and one-half hours. Both acids were present. July 9, 1897, this specimen was moderately active in digesting albumin, and very prompt in coagulating milk.

No. 8.—February 27, 1897, after a fast of six hours, 27 cubic centimeters of gastric juice were removed *from his stomach. It contained both lactic and* hydrochloric acid. July 9, 1897, 131 days after removal from the stomach, it dissolved egg albumin *and promptly coagulated milk. Its digestive powers* were decidedly more active than any of the other specimens. Nos. 2 and 3, however, resembled it very much in activity.

The specimens of gastric juice which were removed after long periods of fasting, showed almost no lactic acid, which goes to substantiate what is now conceded to be a fact, viz., that the stomach in its normal healthy condition does not produce lactic acid.

Another point of importance that I observed in connection with this case, was the rapidity with which the fluids passed out of the stomach. On one occasion, particularly, I remember to have given him four ounces of water by actual measurement. I had at the time an endoscope introduced into his stomach for the purpose of examining the lining membrane of that organ. I held the glass to his lips until he had done swallowing, and then stepped across the room to get a tumbler to catch the fluid that would come from his stomach, and immediately proceeded to drain the stomach. I secured a little less than two ounces of fluid, the remainder of it having been absorbed by the stomach, or forced over into the duodenum. Very little of it was absorbed, as the whole time occupied in swallowing and draining could not have been more than two and one-half or three minutes.

This also goes to confirm observations that have been made by others concerning the disposition of the fluids that enter the stomach from the mouth, viz., that they are rapidly carried from the stomach into the duodenum. It is worthy of note, that in the observations of the fluids taken from this boy's stomach, that the longer the fast, the less the amount of lactic acid; there being only a trace of it in all instances where the fast was twelve hours or more.

A glance at the report will show that the smallest quantity of fluid obtained at any one sitting, was 12 cubic centimeters, or nearly half an ounce.

Again, it will be noted that after a fast of twelve hours, there was as much as 45 cubic centimeters of fluid found in the stomach, which proves that the stomach always contains some fluid.

Another point is, that after 271 days it is well preserved, showing almost no evidences of chemic deterioration.

A NEW TEST FOR LACTIC ACID IN THE GASTRIC CONTENTS AND A METHOD OF ESTIMATING APPROXIMATELY THE QUANTITY PRESENT.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. P. ARNOLD, M.D.
PHILADELPHIA, PA.

In view of the value of the detection of lactic acid in the gastric contents, especially in the diagnosis of gastric carcinoma, the importance of which has been increased by the later work of Boas, and because of the uncertainty and unreliability of Uffelmann's test, I present the following.

The test which I detail is simple and easily applied, the reaction is characteristic, the results reliable. It also affords a method of approximately estimating the quantity of lactic acid present. The test solutions used are:

Solution No. 1, consisting of saturated alcoholic solution gentian violet, 0.2 c.c.; distilled water, 500 c.c.

Solution No. 2, solution ferric chlorid (U. S. P., 1890), 5 c.c.; distilled water. 20 c.c.

The method of applying the test is as follows: Into a small porcelain capsule place 1 c.c. solution No. 1 and add from a pipette 1 drop of solution No. 2. The violet color of solution No. 1 changes to a bluish violet after the addition of the ferric chlorid. To this mixture add drop by drop the filtered gastric contents. If lactic acid is present the color of the solution changes from a *bluish violet* to a *green or greenish yellow.*

Alcohol, glucose, butric acid, acetic acid and phosphates, in quantities below 2 per cent. do not interfere with the reaction as they do in Uffelmann's test. The reaction is not interfered with by acetone or albumoses; sulphuric, nitric and hydrochloric acids do not give the reaction.

Delicacy of the test.—One drop of a 0.02 per cent. solution of lactic acid gives a very distinct reaction. The usual limit set down for Uffelmann's test is the detection of 0.05 per cent. If phosphates are present there is at first a reddish violet color produced, which in the course of a second or two gives way to green. If phosphates be present to the extent of 0.5 per cent. it may take two or three drops of a 0.02 per cent. solution of lactic acid to bring out the reaction distinctly.

To determine approximately the quantity of lactic acid present the procedure is as follows: It is well to prepare a 0.2 per cent. solution of lactic acid to use as a standard. Take two narrow test tubes of equal size and to each add 5 c.c. of test solution No. 1 and 5 drops of test solution No. 2. To one tube add 0.5 c.c. of a 0.2 per cent. solution of lactic acid: the mixture turns green and all traces of violet or blue disappear. To the other test tubes add, drop by drop, the filtered gastric contents until the color is the same shade of green as in the first test tube. Comparison may be made more accurate by equalizing the volumes of the solutions in the test tubes by adding to the first tube as much distilled water as was added of gastric contents to the second tube. To get the percentage of lactic acid present, divide 0.1 by the number of cubic centimeters of gastric contents used.

This is not given as a means of determining accurately the amount of lactic acid present, but with care the amount present can be estimated within 0.1 per cent. and to one accustomed to the use of the test a per cent. as low as 0.05 can be estimated.

3722 Walnut Street.

THROMBOSIS OF THE JUGULAR VEINS.

Presented in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY HELEN BALDWIN, M.D.
NEW YORK CITY.

When Lasègue in 1879 reported a case of phlebitis of the neck, he stated that after painstaking search, he was unable to find a similar observation published, either in France or elsewhere. Since then a number of cases of this kind have been reported, yet they are sufficiently rare to make each one of peculiar interest.

The following record is that of a patient admitted to the New York Infirmary for Women and Children, in the service of Dr. Josephine Walter, to whom I am indebted for these clinical notes.

Ida D., aged 19 years, American, seamstress. Admitted to hospital Nov. 30, 1896.

Family history. Negative. Mother died from an accident, father and two brothers living and well.

Personal history. Measles when 8 years old. Rheumatic fever when 10 years old, with two subsequent attacks on two succeeding years. Her heart has troubled her from early childhood, beating rapidly whenever she ran or exercised vigorously. This became much worse after the attacks of rheumatism, so that now she has palpitation on every exertion. For several years she has not been strong. During the past year the menses have been irregular, and for the past four months she has had amenorrhea.

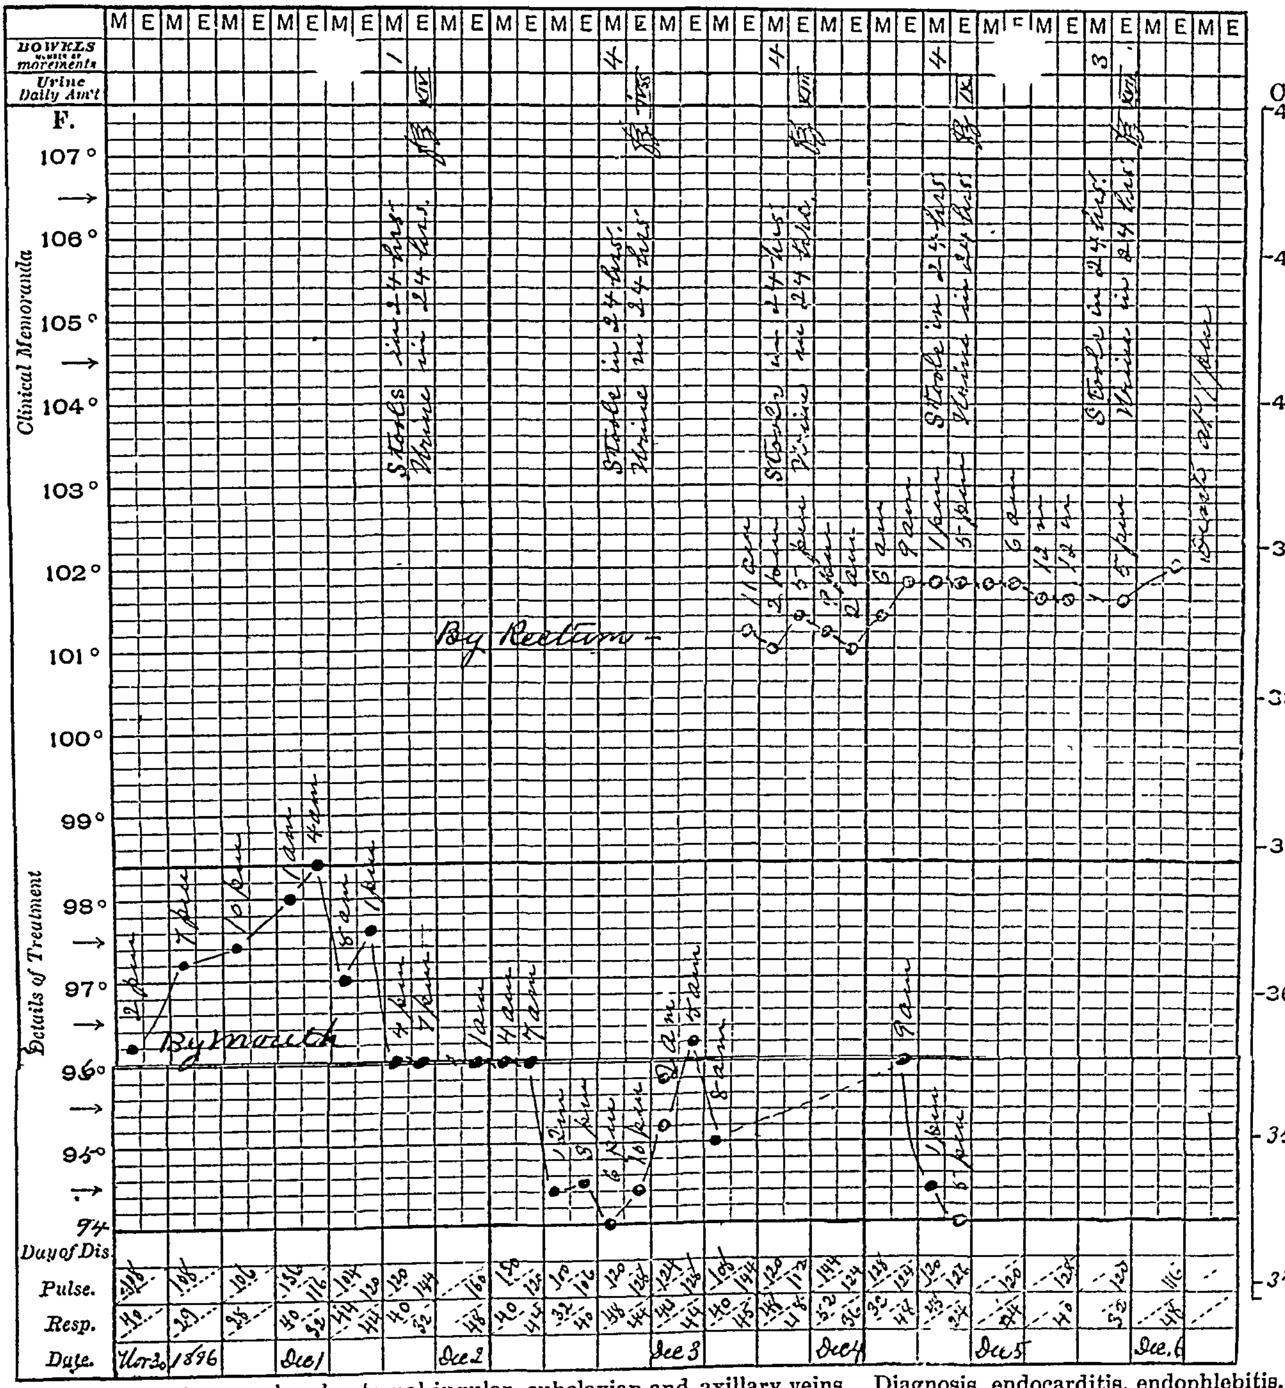
Present illness. About five weeks ago patient noticed that her feet became slightly swollen. The swelling, which was painless, has become gradually more marked since then. A few days ago an aching pain developed in the left axilla and in the left side of the neck. There was also swelling in the neck, which when first noticed would disappear when she sat up, and reappear when she lay down.

On admission to the hospital, the patient appears very weak. There are cyanosis and dyspnea present. Temperature 96.2 degrees F. (35.7 degrees C.). Pulse 108, respiration 40.

Examination December 1. There is lividity of the lips with dilatation of the veins on the edge of nostrils and tip of nose. The pupils are widely dilated. The tongue is slightly coated. The pulse is small, rapid and compressible. The dorsum of the left hand is markedly swollen. Both legs are swollen and pit on pressure. There is marked cyanosis of the skin. The glands in the groin are not enlarged. *Heart.* Left border, 1.3 cm. outside nipple line; right border, 2.5 cm. to right of sternum. Double aortic and mitral murmurs. Apparent dilatation near base of heart, which suggests an aneurysm. Very slight murmur heard in the vessels of the neck. This is out of proportion to the sounds at the base of the heart. A systolic murmur is transmitted down the sternum.

On the *left side of the neck* there is a hard, tender swelling of the lower part of the external jugular vein, which is tortuous. There is a hard lump in the left axilla, extending down the arm for about five inches. The left arm is edemat
quite pale, not cyanosed. The liver is enlarged. Ther
in the abdominal cavity.

Urinalysis. Amount in twenty-four hours 420 c.c. Turbid, reddish brown in color, reaction markedly acid. Sp. gr. 1033, albumin present. Urea 2.8 per cent.; no sugar. Amorphous urates. A few uric acid crystals. Granular, hyaline and epithelial casts.



Thrombosis of internal and external jugular, subclavian and axillary veins. Diagnosis, endocarditis, endophlebitis.

December 2. Patient slept very little during the night. Pulse small but regular. There is a slight puffiness in the palm of the hand, but the edema on the dorsum is less marked today. She does not have earache. The external jugular vein is felt as a cord running up the side of the neck to about one-half inch below the lobe of the ear. There is bifurcation of this cord about half way up the neck. Nothing felt passing posteriorly. The whole left side of the neck is fuller than the right, following the course of the sterno-cleido-mastoid muscle. A prominence, circumscribed, about two inches long, is found on the inner aspect of the arm just below the axilla. The axilla is not as hard or as tender today, and the feet are less edematous. In the lungs, posteriorly there is dulness in the lower part on both sides, and voice sounds are heard over this region. There are fine crepitant râles heard near the bases. Urine in twenty-four hours only about 135 c.c.

The temperature, which was taken by the mouth during the first five days of her treatment, was persistently low. During the first day it reached 98.2 degrees F. (36.8 degrees C.), but after that it varied between 94 F. (34.4 C.) and 96 degrees F. (35.5 degrees C.). On the fourth day it was discovered that while the temperature was 95 F. (35 C.) by mouth, it reached 101.2 F. (38.4 C.) by rectum, and after this, although there was especial precaution taken to avoid an error in registering, there was a difference of from 6 to 7.8 degrees F. (3.3 to 4.3 C.) between the temperature by mouth and that by rectum. (See temperature chart.)

December 4. Pulse seems stronger and there is less tenderness in the arm and hand. There is slight vibration felt in the first intercostal space near the sternum. In the same position there is slight dulness on percussion, which extends to the second intercostal space, and lies a little further to the left than to the right. The first and second sounds of the heart are heard in the first intercostal space. *The character of the pulse is slightly weaker in the left than in the right wrist.*

December 5. Slept a good deal during night, but restless during sleep. At one time coughed up a little blood. Dulness in both lungs posteriorly from the angle of the scapula to the base. On auscultation, over the upper part of chest on both sides, the inspiratory murmur is harsh. Fine crepitant râles are heard at the end of inspiration. The heart murmur is not heard in the back behind the posterior axillary line. Percussion reveals presence of fluid in the thoracic cavity. Thickened cord extending more markedly down side than arm, this morning.

Urine. Amount in twenty-four hours, 510 c.c. Very clear, amber in color, markedly acid. Sp. gr. 1020, albumin 5 grams to liter. Urea 1.5 per cent.; no sugar. Epithelial and hyaline casts.

December 6. Patient failed rapidly, and died in the afternoon.

The postmortem examination was made by Dr. Elizabeth Mercelis. As permission for the section was restricted to that which could be made through the ordinary median incision, the veins of the extremities could not be examined. The record is briefly as follows:

Body moderately nourished. There is general edema, which is most marked in legs and feet, least in upper extremities and chest. On opening the abdominal cavity, there is a free escape of turbid yellow fluid. In both pleural cavities there is also a considerable amount of fluid, with a few firm adhesions between parietal and visceral pleuræ. The apex of heart is in the fifth intercostal space in the mammillary line. In the pericardial sac there is a considerable amount of a clear amber fluid.

The *heart* is much enlarged, being 16.5 cm. in length, 10 cm. in width and 7.5 cm. in thickness. The right auricle is very greatly distended, measuring 13.5 cm. in length. It is completely uncovered by lung. It presents somewhat the appearance of a great distended vein. The left auricle appears normal. Right ventricle shows lines of fat distinctly marked. On the posterior surface is a considerable area of puckering, as of sclerotic change. The vessels on the surface are distended. The ventricle is filled with fluid blood. Length of cavity 8.5 cm.; thickness of wall 1.6 cm. The tricuspid valve is thickened throughout in ridges, and the edge is curled and thickened. There are no vegetations, and no ulcerations. *Pulmonary valves.* Two of these are fairly thin and flexible; along the free edge of the third (the aortic cusp) there is much thickening, having a firm, almost cartilaginous feel.

Left ventricle. The wall is the same thickness as the thickest part of the right. The endocardium is smooth. The aortic valves are thickened on edges. The aorta is soft and smooth. The mitral valves are very much thickened, and adhesions between the different cusps form an almost uniform piece about the ring. There are no ulcerations or vegetations.

The left innominate, left subclavian, and the external and internal jugular veins, extending up nearly to the lobe of the ear, are filled with firm thrombi. There are ragged bits of thrombus extending down into the superior vena cava.

Behind the left auricle, and pressing upon it, is an enlarged, hard lymph-node, 3.7 cm. in length, 2.5 cm. in width and 1.2 cm. in thickness. Extending up each side of the trachea is a chain of enlarged lymph nodes, each about the size of a pea. One of this size is situated at the junction of the subclavian and internal jugular veins. None of these seem to press upon the veins. There is a small extravasation of blood, which has dissected up the left side of the trachea and around the enlarged lymph nodes behind the left auricle. The origin of this blood can not be found.

The *lungs* are congested throughout and both show, on microscopic examination, an early stage of lobar pneumonia. There are areas of infarction in both lungs.

The *kidneys* show cloudy swelling, with scattered areas of old connective tissue degeneration.

The *liver* extends 5 cm. below the margin of the ribs. It is the seat of very extensive fatty change.

The *mucous membrane* of stomach and intestines is congested.

The *spleen* is markedly enlarged, congested and friable.

The large veins of abdomen are free from clots.

The uterus and appendages are normal.

On microscopic examination of the thrombosed veins, the internal and external jugulars present the usual picture of organizing thrombi. There are delicate lines of connective tissue extending into the mass of cells which obliterates the lumen of the vessel. The endothelial cells are slightly increased in number, as are the connective tissue cells in the walls of the veins, but these changes are evidently secondary to the thrombus formation. In the subclavian vein, on the other hand, there is an endophlebitis which is evidently of longer duration and primary to the formation of the clot. Around nearly one-fourth of the circumference the intima is fairly normal, and here the clot lies free in the lumen. The greater part of the intima, however, is much thickened and very irregular along the inner border. In places the lumen is encroached upon to one-fourth or one-third its diameter by this thickened intima. At one portion, the blood clot and intima have become so blended, through the proliferation of intima cells and formation of fibrous bands, extending from the media into the center of clot, that the line of demarcation between them can not be determined. The middle and outer coats are thickened throughout the corresponding portion of the vessel. It appears as if the thrombus formation has been caused by the obstruction to the current of blood caused by this endophlebitis, the stasis being favored by the failure of compensation in the heart.

Bouillard considered that there was a rheumatic phlebitis, similar to rheumatic endocarditis or pericarditis. In this patient's history there is a record of three attacks of acute articular rheumatism, but the last occurred seven years before the present illness.

In 1887, Friedrich Pohl published an article on thrombosis of the subclavian and jugular veins. In this he reported a case, and reviewed the literature of the subject, finding seven cases in which the jugular veins were involved. The records are briefly as follows:

1. Case reported by Pohl, of carcinoma of the vagina, with metastatic growths throughout the viscera. An enlarged carcinomatous lymph node, pressing upon the junction of the subclavian and jugular veins, led to thrombus formation in the left brachial, subclavian and jugular veins, which extended downward for the distance of 1 cm. into the left innominate vein. There were no areas of infarction in the lungs. Death ensued six days after the appearance of the thrombus.

2. An imperfect record of a case reported in 1860, in which the innominate, subclavian and jugular veins were the seat of thrombi caused by the compression of neighboring organs.

3. Ramskill, 1874.—Case of cancer of the uterus, with thrombosis in left external jugular, internal jugular, subclavian and innominate veins and in the superior vena cava. The immediate cause of thrombosis if not given. The patient died one week after the symptoms of thrombus appeared.

4. Walter Smith, 1870.—History of this case not known. The autopsy revealed a large, dark bronchial gland pressing on the superior vena cava, which had caused stasis and thrombus formation in the right internal jugular, the subclavian and axillary and the right innominate veins. There were no metastases, no pyemia or other phlebitis. The heart was dilated, the tricuspid valve thickened, the other valves normal.

5. Clodomiro reported a case of phthisis with cavity formation at the left apex, and adhesions between the pleura and left innominate vein causing stasis and thrombosis in the subclavian, axillary, deep brachial, cephalic, basilic and jugular veins. The patient died fifteen days after the appearance of the clot.

6. Moizard, 1875.—A case of sarcoma of the mediastinum, obliterating the lumen of the superior vena cava, and causing thrombosis of this vessel as well as of the right innominate and right external jugular. The patient died after three or four months.

7. Robert, 1880.—A patient in the later stages of "lung disease," with an enlarged lymph-node, pressing upon and adherent to the left innominate vein, with thrombosis in this vessel and in the internal jugular. The patient died four months after the thrombus formed.

8. More, 1882.—A case of aneurysm of the ascending aorta, with pressure on the superior vena cava, with a large clot occupying the right innominate, subclavian and external jugular veins. Death eight days after the appearance of the thrombus.

Besides these cases reported by Dr. Pohl, I have found records of the following:

9. Lasègue, 1879.—A case of phthisis with thrombosis of the external jugular, subclavian and humeral veins. The thrombus softened and all symptoms of phlebitis disappeared ten days after its formation. No direct cause was discovered in this case.

10. Languebeck, 1881.—A case of tumor of the neck, adherent to, or growing from the internal jugular vein, with thrombosis at that point. Operation with removal of tumor and of thrombosed portion of vein. Recovery. Tumor supposed to be a syphilitic gumma.

11. Pettit, 1882.—A case of yellow fever followed by symptoms of pyemia. At autopsy the right subclavian, external jugular and cephalic veins were occluded and filled with coagulated blood and fibrin. There were areas of infarction and metastatic abscesses in the lungs. Death twelve days after clot formed.

12. Lejard, 1882.—A case of caseous pneumonia with cavity formation. Thrombus, which was supposed to be due to the cachectic condition of the patient, formed in the external jugular and its anastomosis with the anterior jugular, and in the deep veins of the forearm. Death two days after the formation of the clot.

13. George Wilkins, 1883.—Case in which the superior vena cava was converted into a firm, fibrous cord with organized thrombi extending into the innominates and internal jugulars on both sides. The thrombus was thought to be due to an endophlebitis, caused by strain. Death four months after the symptoms of thrombosis in the neck.

14. Kelsch, 1887.—A case of carcinoma of the stomach. Thrombi found in the left external jugular and subclavian, also in the inferior vena cava, from the renal vein to the bifurcation of the vessel, and in the iliac and crural veins on both sides. The patient died one month after the formation of clot in the external jugular vein.

15. Picot, 1884.—Case of phthisis, with the brachio-cephalic trunk of left side obliterated by a clot which extended into the jugular and axillary, but not into the vena cava. This thrombosis was due to compression by a hypertrophied lymph-node.

16. Comby, 1892.—A case showing symptoms of occlusion of the superior vena cava with thrombi in the left external jugular and left axillary veins. The cause was not found. There was a history of syphilis, but no improvement under antisyphilitic treatment. Under treatment with Fowler's solution the patient made a perfect recovery.

17. Younge, 1895.—Case of thrombus formation in superior vena cava, left innominate and jugular veins and left lateral sinus, occurring in Bombay. The condition probably due to exposure to extreme heat, with possibly malarial infection.

18. Gatay, 1896.—A case of rheumatic phlebitis, with death following thrombosis of the subclavian, jugular and innominate veins.

19. Renouard.—Case of rheumatic phlebitis, involving internal jugular and subclavian veins.

20. Nicolle, 1897.—A case of endocarditis, attacking the mitral valve with phlebitis of the external jugular vein.

I was unable to examine the original papers in the last three cases. In all the above cases, the thrombus was found in the jugular vein alone, or in that, together with the larger trunks below the vein.

In the internal jugular there may also be thrombus formation secondary to diseased conditions in the lateral sinus. Indeed, Gatay makes the assertion that phlebitis of the deep jugular vein is regularly secondary to inflammations of the sinus.

In 1880, Lemoine reported a case of death from thrombus formation in the lateral sinus and internal jugular vein in a tuberculous patient, the other veins of the neck being normal.

Allport, in an article on "Purulent brain deposits and phlebitis and thrombosis of the cerebral veins and sinuses following ear disease," found that out of the 169 cases which he reported, in nine the internal jugular was involved. All of these nine died.

Pitt in 1890, in an analysis of fifty-seven cases of ear disease and of the complications which led to death, found that in eleven of these cases the clot extended into the internal jugular, with death from pulmonary pyemia.

Herczel in 1893 reported a case of thrombosis of the transverse sinus and jugular vein, with recovery after operation.

Jansen, in an article published in 1893, on brain thrombus following middle ear disease, found the internal jugular vein involved in twelve out of 215 cases reported.

In studying the causes of thrombosis of the jugular veins, from an examination of the above records, we find that, as in any situation, the conditions favoring coagulation are: 1, sluggish or arrested circulation; 2, inflammatory processes in the vein due to injury or to bacterial invasion, or to the presence of irritating substances held in solution in the blood; 3, morbid conditions of the blood rendering it more readily coagulable.

Out of the thirty-four cases found, in eight, or nearly a fourth, there was pressure on the vein leading to stasis. In sixteen, or nearly half, there was a grave blood dyscrasia, three having carcinoma, one, sarcoma; six, tuberculosis; two, tertiary syphilis; one, pyemia following yellow fever; two, acute articular rheumatism, and one probably malaria combined with changes due to heat exposure. In five cases there is endophlebitis, three probably due to rheumatism, one to syphilis and one to injury. In thirteen cases, or 38 per cent., the condition is secondary to middle ear disease.

In only one of these cases, that of syphilitic gumma, does the morbid process seem to have originated in the jugular vein itself. In the others it formed secondary to thrombus in the innominate vein, extending away from the heart, or secondary to clot in the lateral sinus, extending toward the heart. In many of the reports it is stated that the clot was adherent to the vessel wall, showing that there had been an endophlebitis, either secondary to the thrombus formation, or primary and leading to it.

The symytoms are those of phlebitis in any vein. Following the description of Gatay, these are pain, tenderness, edema, venous arborization, the presence of an indurated cord, and a line of redness if the vein be superficial. In one case the edema was limited by the median line of the neck. In that of Dr. Walter, there was a peculiar subnormal temperature by mouth, while that by rectum was elevated. The general symptoms are usually masked by those of the original disease.

While the prognosis of venous thrombosis is, in general, not very grave, it would seem from a study of the above cases, that in the jugular veins it is seldom found excepting in the last stages of fatal diseases. In sinus thrombosis, the involvement of the jugular vein makes the prognosis much more grave from the liability to pulmonary infarction. In only four of the cases noted above was there recovery. One, occurring in the course of phthisis, made a spontaneous recovery; one, of doubtful etiology, recovered under the use of Fowler's solution; one of syphilitic tumor recovered after operation, as did one of sinus thrombosis following ear disease.

MEDICINE AS AN EXACT SCIENCE.

Presented to the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY W. J. K. KLINE, A.M., M.D.
GREENSBURG, PA.

The study of the human body involves the consideration of the framework, the muscular, vascular and nervous systems. In these we find the highest development in mechanical and physical skill. The composition of the structure is the assimilated material secured from the nutritive substances ingested and conveyed to the various parts of the body. The whole system is a laboratory of chemic evolutions and synthetic combinations presided over by the mysterious monitor called life. Science, in the supreme sense, is applied in the construction of this handiwork by the creator of a mechanism unequaled in beauty, symmetry and potentialities, far beyond the highest achievement of the finite being, man.

It is man's privilege to investigate this creation and interrogate every step in its development, in its normal existence, in its decline and destruction. To do this it is, however, necessary to follow along the line which governs its existence and keep in view that its nature is a scientific problem of the most intricate character.

In health the whole being moves on without the slightest deviation in its activities, and if the scientist understands its workings he is prepared to note any change that may take place should this misfortune occur, and from the scientific study of the physiologist we pass over into the realm of the pathologist when some destructive energy has interfered with the normal condition of the body.

The physiologist considers every organ and every tissue and every element in the formation of tissue and in the secretion of the fluids of the body, before he is fully conversant with every phase in the existence of the human being.

On the other hand the pathologist marks every deviation from the normal and notes the abnormal formations, the accretions vitiated, the germs developed by the ptomains in the system, and formulates their chemical elements, and observes the reasons why the conditions of health have been disturbed. To illustrate, the physiologist tells of the presence of certain secretions in the stomach, in the liver, in the many organs of the body, so that we may know what is required to keep the body in a healthy condition and, aided by the analytic processes of chemistry, we may know the requirements to maintain the health-giving influences necessary to this existence. The pathologist aided by chemistry notes the departures from the laws of health and is prepared to demonstrate the necessity of a change in the assimilative and elaborative activities of the human system.

In this work the pharmaceutist comes forward with the remedial agencies of his laboratory. Each medicine having been duly analyzed and formulated, the therapeutist may now take cognizance of the relations between the disorganized properties composing the tissue of the body, the causes that lead to disease, and the chemically indicated elements necessary in *replacing the wanting or disorganized elements necessary* to health.

In advocating this method for the establishment of the laws necessary to the scientific treatment of disease, and in devoting our best energies to the practice of medicine as an exact science on the lines herein advocated, nothing more is done than what is the outgrowth from the experience in other but more common fields of investigation.

Take for instance the intelligent farmer in the cultivation of his fields. He notes the character and quality of the soil, and until he has chemically investigated its constituents he can not tell to what fruitage it is best suited or what may be necessary to restore it to the proper condition for the growth of luxuriant crops or blooming foliage.

The iron furnace does not gleam with its dazzling flame, neither does it glow with its intense heat, nor does the white stream of its liquid metal flow from its imprisoning walls until the chemist has tested every ore, every coal, every limestone and manganese, and every element tending to give the result. Having determined by chemic investigation, we know absolutely what metal may be produced.

The value of the scientific investigation necessary to the highest attainments is still better exemplified in the latest methods employed in the management of obtaining gold from refractory ores. There was a time and not long since when great fortunes in gold ore were thrown aside because the means of separating the gold from the sulphurets of iron, copper and zinc was unknown. It was not until the chemist, by years of toil, found the key that unlocked the treasures hidden in the tomb of buried ages.

The cyanid process, together with the aid of electricity, now extracts gold that once was lost to the world and where not lost required great labor and often unrequited efforts to secure it only in part.

May we not, then, learn something from the scientist whose stimulus is the acquisition of wealth while the profession of medicine is the hand-maiden of love, whose mission is to lengthen out the cord that binds us to life and set forward the mile-stone on the journey that moves through devious pathways to the unknown.

In a paper prepared for the Medical Society of the State of Pennsylvania, the arrangement of the remedial agents were indicated according to their formulas and it was shown that this was possible and in the line of progress. From the investigations made, it appears that medical agents possess properties which are similar wherever the formulas are expressed in like characters. When, therefore, we possess a complete system of definitely arranged pharmaceutic agents, according to their chemic formulas, then we are prepared to treat disease upon the same certain methods applied in the chemical laboratory. The time will come when we shall also have the formula of the condition of the organ of the patient in health. We will also have the pathologic state expressed in a legible way, and then as skilled practitioners we will have a positive remedy with which to correct the abnormal condition under consideration, because we have known factors in the problem to be solved.

There will then be no doubting, guessing or hoping for a plausible diagnosis or prognosis, but the medical profession will be engaged in doing a work which deals with facts and will rank as the most learned among all the erudite of the human races. This work *is already accomplished in part.* The anatomist goes to the beginning of the formation of the material constituting the several parts of the body. He expresses the elementary composition in chemic language. The physiologist in his functional investihad control of the doctors and army surgeons, "so that arms and legs would not be amputated wholesale, and that in general no amputation should be undertaken until mortification had set in, for which the captains were also responsible." If the surgeons did not do their duty, did not give the patients food regularly, or if they appropriated anything belonging to the hospital, then the captain was "to immediately arrest the guilty man, whoever he might be, and put him in chains," whereon the case would be prosecuted with the greatest severity. One consequence of the above mentioned conversation between the king and Zimmermann was that the court counselor Fritze of Halberstadt, who in an anonymous article had exposed with great candor the evil conditions of the Prussian military hospital system, was called to Potsdam by the king, and about a month before his death (1786), was charged with the management of the field hospitals. He said in that article ("Das konigl. Preus. Feldlazereth u. s. w.," 1780), among other things: "The Prussian army in Saxony consists of 72,000 men and the Saxon army of 22,000. Of the former about 4,000 have died in the hospitals and of the latter only 48. What a striking comparison! Certain conditions must necessarily exist in the Prussian army and their hospitals to have caused the greater mortality," and further, "Just the same old methods in economy and medicine which were followed in the war from the year 1756 to 1763 have been followed in this last war, to the destruction of the patients and the ridicule of the whole civilized world, without use having been made of the fruitful experiences of twenty years. . . . The honest fraternal Saxon showed his sympathizing comrades the misery and death which his brethren, the Prussians, often innocently suffered, and the Prussian physician, full of zeal and energy, stood by ashamed and could answer nothing but, 'I can not help it.'"

Let us follow our Prussian colleagues into the Seven Years' War. At the pinnacle of the medical world stood the general staff-physician Cothenius, who, with the two army physicians representing him, exercised the highest authority over the hospitals, physicians, etc, while the surgeon-general directed the surgical part. In a second army the chief staff-physician and the second surgeon-general held commanded. Schmucker, Bilguer and Theden were surgeon-generals. Under them were all the surgeons in the army; first of all the so-called supervising surgeons, staff surgeons, chief surgeons and pensioned surgeons who treated the wounded in the hospitals. Subordinate to these were the ordinary army surgeons who were engaged with cases of internal sickness, as well as in attending the wounded, and received half the salary of a chief surgeon. When it came to battle, a surgeon-general with a few supervising and lesser surgeons, took a position as near as possible to the fighting troops, in order to bandage the wounded on the battlefield. Ditches and other protected places served to cover them while they worked. All the Prussian military physicians were exposed to the fire. Schmucker received a shot in the chin and another in the neck, at Soor, while he was applying a bandage, and later, as surgeon-general, in the battle at Prague, a shot on the edge of the orbita, so that he fell from his horse unconscious and spat blood for four days. In spite of severe pain he did not spare himself from attending to his many duties. When the first bandage had been applied, the wounded soldier was given diluted vinegar (which every Austrian soldier had in his canteen, while the Prussian carried brandy with him), saltpeter, or other medicine to ward off inflammation and to avoid a violent wound-fever. If necessary the wounded soldier was bled and then taken to the *movable hospital.* These were for the most part located in castles, churches or granaries in the neighborhood of the principal magazine, the military chest and the field bakery, so that the patients were under protection, were well cared for and could be easily transported. Here, under the supervision of a surgeon-general, the higher surgeons and the German and French pensioners, an accurate examination took place, the necessary dilations and incisions were made, bullets and splinters were extracted and trepanning and amputating were done Often an extracted splinter became a relic. Prussian as well as Austrian officers had their extracted bones polished and set in a ring or cross, beset with brilliants, and the name and date of the battle engraved thereon in black. Those sick with internal diseases were separated from the wounded and taken to special hospitals where staff physicians were in attendance. In simple surgical cases here either a higher surgeon was called in consultation or the patient was removed to a surgical hospital. The staff physician visited the patients twice a day, kept journals and supervised the diet and ventilation. In case of a lack of physicians the higher surgeons took charge of internal ailments; on the other hand, the physicians visited the hospitals of the surgeons if the first or second physician gave an order to that effect. The sick and wounded remained in the movable field-hospitals until they could be brought to a permanent hospital. It was a great misfortune that after the battle the wounded were not immediately taken in charge, because often a safe place for the field-hospital had to be first sought out; sometimes four, sometimes six days passed before the wounded were all brought together. At Prague one side of the city was being stormed and the hospital was located on the other side on the white mountain, and there it was almost eight days before the last of the wounded came into the hospital. The consequence was that, as Schmucker complained, most of the amputations were not made until a few days after the battle, and then as a rule resulted fatally, while many soldiers were so weakened by the transportation that an operation was no longer possible.

Transportation was in a bad condition under Frederick the Great. The instruction on this point in his "Unterricht von der Kriegskunst an seine Generals," reads: "When the victory has been gained I command that a detachment shall be made of those regiments which have suffered most, that the wounded shall be cared for and brought to the hospital, which must be prepared beforehand. Further, in caring for the wounded let men not forget the human sympathy toward those of the enemy." As a rule they used the empty flour and provision wagons, which had also to bring forage, to convey the patients to the hospital. "The dysentery patients were for the most part carried to the hospitals in the wagons which were to take back rations for the army. Into these same wagons which were filled with the foulness of the disease and the rank poisons of the prisons, the bread for the healthy soldiers of the army was loaded, even on the same day" (Fritze). If the army decamped immediately after a battle there was necessarily the greatest haste in bandaging the wounded, for they were taken along. Thus it was in 1760 after the battle of Liegnitz, where the king commanded that all the wounded be immediately bandaged and brought to the wagons, because the army must march twelve miles on that same day. Only two hours were allowed for the bandaging. When the time had expired the severely wounded were laid on the baggage, bread and provision wagons. Those slightly wounded were obliged to march near by, but without their equipments. That was indeed a relief in itself, since the Prussian infantryman had to carry sixty-five pounds on the march. There were still five hundred, mostly injured in the upper extremities, who were unable to march but found no conveyances. Schmucker decided quickly, and obtained from the king a command to have a regiment of dragoons dismounted. Within half an hour all the wounded were on horses and the dragoons marched beside them. In this way the three days march to Breslau was accomplished. When it was necessary they even transported those who had lately suffered amputation. For these Schmucker had the field-bed of an officer fastened to two poles, and handles attached, so that it could be carried by two horses. Often many days elapsed before the wounded, attended by the company army surgeons, arrived at the *permanent field hospitals* (Hauptlazarethe), where they remained until their complete recovery. The king or the commanding officer decided on the location of these, whenever possible in large cities and not too far from the army. They took for this purpose castles, churches, monasteries and barracks. In the Seven Years' War such chief hospitals were in Breslau, Glogau, Stettin, Dresden, Torgau and Wittenberg. They were directed by a staff officer, who had the general supervision of the entire management of the hospital, especially of the supplies and nursing and of the men ordered into the hospital. Under him inspectors and commissaries paid the wages, took care of the apparatus and kept the lists of the stock of the hospital. Every regiment that had many sick therein ordered an officer to the hospital; in case of a few sick, an under-officer; and these had charge and reported concerning their own people. Also the regiments after a battle gave several company surgeons over to the hospitals that they might not lack help; as soon as they could be spared they were sent back. Each under-surgeon cared for twenty to thirty wounded or fifty to sixty inwardly sick, who lay upon straw sacks, with the exception of the severely wounded who had beds. Four to eight under-surgeons were under the command of a supervising surgeon who instructed them, made daily visits, treated those most severely wounded and performed the operations. Only in severe cases and important operations was the over-surgeon obliged to ask advice of the staff-surgeon and follow his directions. The lower surgeons assisted, attended to the night watching, had to administer the prescribed medicines four times a day, and keep a journal, but they could undertake nothing of importance. Their business was also more or less that of the hospital attendants and nurses of the present day. Only the most skilful among them was sometimes permitted, under direction, to make an incision or to trepan. So-called waitresses (Aufwäterinnen) attended to the fomentations, etc. The surgeon-general had supervision; he visited the hospitals unexpectedly, was consulted orally and by letter and frequently performed the most important operations himself. At eleven o'clock in the morning everything had to be in order, because then, by the order of Cothenius the entire hospital force, physicians, surgeons, commissaries, apothecaries and officers met in conference to discuss hospital matters. (In later years the so-called head hospital commission had charge of the directors of each hospital: this commission consisted of the general staff physician, the first surgeon-general and a staff-officer, who at the outbreak of the war ordered everything for the mobilization, appointed physicians and surgeons and met daily to decide together on everything. 1787.) A report was made to the first surgeon of the army, as well as to the surgeon-general, and twice a month an accurate list of patients was furnished, so that from all the lists they could obtain a summary of all the sick in the army. One evil result of the recruiting system instituted at that time, which appeared especially in the examination of those suffering from internal diseases, was the different languages spoken among the sick, since there served in the army of Frederick the Great, Russians, Danes, Swedes, Poles, Hungarians, Dutch, Turks, Italians and French.

"The Prussian soldier kept his weapons with him as long as he lived as an evidence that he was born to the use of them." From this point of view he enjoyed in the hospital, during the Seven Years' War, a freedom which was very injurious to him. He received wages, bread and meat, in the same amounts as when in active service, and was master concerning his mode of living; nothing was taken from him. The physician could only give him friendly advice in the matter of his diet; he had no further authority; the Prussian soldier also guarded with great care the freedom which his king had extended to him. In this respect the Prussian hospital regulations were behind others, for in Austria the soldier was required to observe a prescribed diet and, as in England and France, he received no wages so long as he was cared for in the hospital. After Theden had taken the lead in the improvement of the hospital of his artillery corps, the matter of diet was (1787) arranged by a new regulation in Prussia. From that time on the physician prescribed the diet. He fixed a full portion at three-fourths of a quart of meat soup with barley or rice, one-half pound of meat and one and one-half pounds of bread. Besides, he prescribed half and quarter portions; if necessary, wine also, which formerly the physician had to pay for out of his own pocket when he ordered it. Wages and cash were taken from the soldier and deposited.

The *apothecary shops* were attended by a chief field-apothecary, several field-apothecaries and assistants, a continuous control of whom made peculation scarcely possible. Since the first army physician alone made the selection of medicines, for the most part only such were found as agreed with his views. The formula which Cothenius introduced as well for external as for internal remedies were often nonsensical mixtures and frequently contained ten or fifteen ingredients. For the sake of curiosity we will quote a menstruum of vulnerary water, composed of thirty-four substances, which was used by Bilguer; it was an aqua vulneraria s. sclopetaria *vinosa pharm. Parisiens.*

S. Sclopetaria vinosa pharm. Parisiens:

Rec. Radicis symphiti majoris, Foliorum ejusdem, Bellidis maj. et minoris, Bugulæ, Saniculi, Betonicæ, Scrophulariæ, Plantaginis, Agrimoniæ, Hyperici cum summitatibus, Vincæ per vincæ, Hederæ terrestris, Artemisiæ, Veronicæ, Verbenæ, Telephii majoris, Millefolii ana uncias quatuor—Salviæ, Angelicæ, Tanaceti, Absinthii, Chelidoniæ majoris, Fœniculi, Aristolochiæ clematitidis, Menthæ, Hysopi, Nicotianæ ana uncias octo—Rutæ, Chamomillæ, Scordii, Majoranæ, Rorismarini ana uncias quatuor—Summitatum et florum lavendulæ, Origani, Caliminthæ ana uncias sex—Macerentur per quatriduum in Vini generosi libr. quinquaginta ponderis civilis, postea destillentur ad dimidias.—Si spirituosa expetitur hæc aqua Vulneraria, loco Vini, herbis modo præscriptis spiritus Vini rectificati super affundantur libra quinquaginta, atque destillentur.

There is still in existence an apothecary's outfit of Frederick II. which was found on the battlefield at Hochkirch in 1758, contained in a spacious cabinet inlaid with brass. Purgatives occupied the principal place (rhubarb, jalap, aloes, sulphate of magnesia, Rochelle salt, etc.), then many emetics (ipecac, tartar emetic), antispasmodics (spirits of ammonia, camphor, musk), antimony and iron preparations, many powdered herbs, opium and a mass of remedies now entirely antiquated. For surgical purposes there were especially balsams (balsam of Peru, of Mecca, of white amber, etc.), besides much sugar of lead and a great quantity of sublimate. Half of the compartments in this apothecary's cabinet are empty. An absurd custom, originated by the Frenchmen in the Prussian army, was the giving of French names to all the materials for bandaging in the field hospitals, although not a single one of the army surgeons could pronounce or write these names correctly. For example, Bilguer taught that the bandage for the stump of the upper arm was called *le bandage pour l'amputation du bras*, and the plane for the exarticulation of the elbow, *le doloire pour la luxation du coude.*

It might be of interest to inspect some certain hospital more closely, and we will choose for that purpose the *siege hospital of Schweidnitz* which the surgeon-general Schmucker erected in 1762. The large village of Neudorf, a short mile from Schweidnitz and half a mile from the depot was selected for the purpose. There ten days before the opening of the trenches Schmucker arrived with a great number of staff, chief and pension surgeons, more than sixty hospital surgeons and many stores, so that he could put everything in proper order. Immediately four great massive barns belonging to the court of a noble were cleaned and bunks built a foot above the ground. Schmucker quartered himself in the master's house with the staff physician, hospital inspector and the field apothecary. Four large rooms in the village were reserved for those injured about the head. The patients with internal diseases were taken into the barns before they could be transported to Breslau, the wounded officers were put in the other houses. At the entrance to the trenches they built a great wooden shed, which was protected from the bullets of the enemy. Into this depot for the wounded ("Blessirtendepot"), all those wounded in the trenches were brought, the first bandages were applied, and when necessary they were bled. As soon as a number of wounded were gathered they were taken early in the morning or in the evening in wagons to the siege-hospital. A regiment surgeon with four company surgeons kept watch every night in the depot and were relieved after twenty-four hours. In the hospital itself a staff or chief surgeon, with a pensioned surgeon and four hospital surgeons performed continuous watch service in order to immediately provide for the newly arrived wounded; if there were any among them in a very serious condition the matter had to be at once reported to the surgeon-general. Each directing surgeon had about fifty wounded, with five hospital surgeons under his supervision. Schmucker detailed a few surgeons for the patients having head injuries, and relieved them from all other work. A journal was kept in each ward in which the course of the disease was recorded often from hour to hour. This day-book could easily be kept up in Schweidnitz where they worked leisurely, since it was not crowded with too many cases at one time, as it was not possible to do at the great battlefields. Every five days a number of wounded were sent to Breslau on wagons, but those having injuries to the head and the seriously wounded were kept in the hospital. When at the end of September the severe cold began with snow the patients could no longer remain in the barns, so a great sheep-stable had to be cleaned. Twenty men were occupied eight days in carrying out the manure, and cleaning and purifying everything. In the four great doors and in various places in the walls Schmucker had square holes cut and windows inserted. There the patients were sufficiently warm, suffered less from draughts than in the barns and were very well satisfied. The stable was fumigated once a day and aired after every bandaging.

Although the Prussian surgeon-general insisted on cleanliness and fresh air in the field-hospitals, and ordered that the patients be removed into new rooms every three or four weeks in order to clean and air the old ones, and had windows and doors opened and the ventilators of Theden used, and would not tolerate too high a temperature in the rooms, yet this common sense was by no means general. Moreover, there was crowding together of the sick. In the hospital in Dresden "the beds of the patients were usually crowded so closely that one straw bed touched the other and there was scarcely enough space left to allow one to pass between the rows. Indeed, very often one was obliged to step over the patients, and the feet of one were almost in contact with the head of another. Even when the hospitals were sometimes relieved by the transportation of many patients it was rare that they could sweep or scour the floor" (Fritze). The consequence was that a violent epidemic prevailed in the hospitals and many attendants and army surgeons died. Another disadvantage in the field-hospitals of which Bilguer and Baldinger especially complained was the frequent transportation of the patients to and fro, which cost many a one his life, and also the frequent change of the acting surgeons, in so much that a wounded soldier often came under the hands of four, six, ten and more before his recovery.

(To be continued.)

DISCUSSION ON THE SEVERAL PAPERS ON TUBERCULOSIS.[1]

Dr. DENNISON of Denver, Colo.—We are indebted to Dr. McFarland and Dr. Rochester for their excellent papers read this morning, and I wish particularly to commend Dr. McFarland for his excellent statement of what tuberculosis is. I have no controversy with those gentlemen as to their treatment or the results of their experiments. I object to Dr. Cohen's warning against seeking after a specific for tuberculosis as if it were a will o'-the-wisp. I commend the work of Prof. Klebs, Dr. von Ruck, Dr. Trudeau, and those men who are in search of a specific for tuberculosis. Their work is to be commended because it is painstaking, and for the hard lines which they are following. In the first place it seems to me impossible that we can prove anything by testing tuberculin on healthy persons, for tuberculin can only affect individuals previously infected with tuberculosis. The assertion of one of the gentlemen that there is such universal infection in the human race is to my mind proof that immunity exists to a certain extent, otherwise all must die. Each one of us must have a certain proportion of immunity, yet if immunity exists it is only relative. It is relative immunity, then, which we have in mind when we put in an argument for immunity.

---

[1] See preceding JOURNALS for the papers read. The stenographer's copy was not received in time to print with the papers.—ED. JOURNAL.

I have no controversy with the gentlemen who emphasize the necessity for individualizing patients and the necessity of building up the resisting cells. I am myself under the ban of having said that the good results which I obtained from the use of antiphthisin and antituberculin were due partly to the climate of Colorado. I admit the charge that we have a great help in fighting tuberculosis in that fact. Altitude is an important element. I am, too, as much a crank on exercise in tuberculosis as anybody. But I approve of the efforts of gentlemen to discover something which will produce immunity. From experiments now being made, I believe it exists in the extract of dead bacilli. Prof. Koch's new remedy, I believe, is made from the extract of live bacilli. But somewhere there is an antitoxin influence in the bacilli themselves which, in very small repeated doses, will eventually set up an immunity in the system which increases the natural immunity. We are thus coming to recognize that all infectious diseases are to be fought by either artificial or natural antitoxin, and, through experimentation on animals we are yet to learn just what that element is and how it can be obtained. Prof. Klebs and Dr. von Ruck are getting nearer and nearer to it every few months.

Dr. Klebs of Asheville, N. C.—Concerning this question there are two kinds of work which are most important; one is work in the laboratory, the other is clinical work. These are to be separated absolutely. But what has been found in laboratories can be tried in hospitals. To assert the contrary is to put a stop to all scientific result. Regarding antitoxin, etc., tuberculosis is so various in its forms that, to say a remedy, even after long observation, will cure it every time, is not possible. We must have animal experiments. To judge simply by clinical observation is not possible. Many remedies have been praised too quickly simply because the patient has improved for two or three weeks. In tuberculosis that will not do. We must have many observations on animals, and long study. We must first go to the laboratory. Clinical results come later. All sorts of remedies have been brought forward, some of them without any scientific basis whatever. The list includes many which are not mentioned in our pharmacopeia.

Hygienic management has been properly commended, but it is not so easily carried out. We can say to our patient, go into the fresh air and stay there, and live on a proper diet. But it will fail simply because your instructions will not be carried out a sufficient length of time, and time is most important in tuberculosis. If we want to cure tuberculosis we must treat the constitution of the patient, or he may become infected again after five or eight years and the whole process have to be gone over again. To enforce hygienic rules we must have suitable surroundings and keep the patient under observation for a long period. This treatment has been much perfected in this country. Dr. Trudeau stands foremost with his sanitarium in the Adirondacks, where his patients are treated according to the strictest hygienic principles. After they have spent a year there, they go out and observe those rules outside. They know how to take care of the expectoration, they know everything which will tend to prevent infection of other people and themselves again. To bring hygienic care forward properly it is necessary to have institutional treatment, and the State can do in this line more than the individual. If an Association like this will take steps to promote this idea the death rate from tuberculosis will certainly diminish.

Dr. Herrick of Cleveland, Ohio—What I shall say at this time will be somewhat in controversy with opinions which are prevailing, and I must beg your indulgence and ask your consideration in the matter. The whole doctrine of today, on tuberculosis, rests upon the theory that it is an infectious disease due to a specific germ. The doctrine has come into vogue the last twelve or fifteen years. We knew something about tuberculosis twenty years ago. I have practiced medicine more than thirty years, and have been a clinical observer and a fair student of the question, and I must say that I belong to the doubting Thomases. I can not fully accept the idea of tuberculosis being due to infection. I am inclined to regard it rather as a disease due to disturbance of the blood-making process, to disturbance of the digestive organs, to the air we breathe, and to a number of factors. I never look for a specific cause of this condition. I think it is futile to do so. The gentleman who has taken his seat has admitted as much—a high authority for the bacterial idea of the disease. I have no expectation of finding a specific in the form of tuberculin or anything else. We must go back to physiologic principle.

Dr. J. M. Allen of Kansas City, Mo.—The life of all bacteria depends as much upon other life as does that of human beings. Now in the human family about one-fourth furnish pabulum on which tubercle bacilli can live and develop. That, I think, is in accord with statistics of today. The tubercle bacillus begins its attack upon some structure, and causes certain pathologic changes which are fixed and definite. The aim of treatment is destruction of this pabulum by means of which the germ has its existence. If that pabulum is not present, you may inject the germ into the blood and it will die right there. Those who believe in dietetic treatment often ignore all else that is hygienic. That is not fair. We use all—hygiene, diet, climate, etc. The theory of the climatic treatment is that the elements necessary for the growth of the tubercle bacilli do not exist; for instance, in Colorado. Hence Colorado is an excellent climate for the consumptive.

I have tried the Paquin serum treatment in four cases. One patient has recovered. Why do I say that? Simply because he has been under observation for two years and not a single bacillus can be found. They were abundant before. I do not say that this person, if tubercle bacilli should become located in his lungs, would not again take the same disease. You can not yet say that of diphtheria. We are looking in that direction. In another case the tubercle bacilli have become attenuated, and the man is now performing hard work and is improving every day. Still he has not fully recovered, and is under treatment. The other two cases were much benefited, but in them there was large destruction of tissue.

I conclude that with serum coupled with hygiene, the use of creosote and tonics and every other thing which can be brought to bear, and sending the patient to a climate where tubercle bacilli have not the conditions for their growth tuberculosis can be cured, provided these measures are adopted early.

Dr. J. N. Upshur of Richmond, Va.—I believe the underlying factor in tuberculosis is malnutrition. I believe that immunization, which exists in the majority of the human race, exists because these is not a fertile soil in which the bacilli can develop. We of the South have an object lesson in the negro. It was an exceedingly rare thing, before the war, to see a negro with phthisis. We saw cases where there was scrofula upon the neck where it was inert, but it was rare for it to develop in the lung. Since the war, the tendency of the negroes has been to migrate to the city, where their conditions are different from what they were before the war when they had fresh air and abundant nutritious food, eating a great deal of liver and bacon and corn bread, with an abundance of vegetables, having warm clothing and plenty of light in their rooms,—since they have gone to the city where they are overcrowded, where they are frequently out of work, where they are frequently thrown upon the city government for support, where many have become thriftless, in summer living upon watermelons and spending what money they have upon what they call "society" for the purpose of having a big funeral when they die; as a result of these unwholesome conditions and malnutrition tuberculosis of every variety has become rife among them.

Dr. George M. Sternberg of Washington, D. C.—I must express my surprise on hearing, at the present day, a gentleman talk about the doctrine of the infectiousness of tuberculosis. I think one might as well talk about the doctrine of there being an American Medical Association. The demonstration has been made long since. It is satisfactory to the profession. It can be repeated for the benefit of any one who desires, at any time and in any pathologic laboratory, that the tubercle bacillus causes unmistakable tuberculosis in suitable animals.

As to the question of susceptibility and immunity, the general laws do not differ from those relating to other diseases. There is a specific infectious agent. There can not be tuberculosis without a tubercle bacillus, any more than there can be any other infectious disease without its specific infectious agent. But there must be something more for infection. There must be a susceptible individual. We all know that there is a great difference in the susceptibility of individuals; and that that difference depends partly upon inherited characteristics. Certain animals are more prone to it than others. The susceptibility depends partly upon the early life. Leading a sedentary life, being shut up in close rooms—those individuals who have not the necessary tone which is obtained by living in the fresh air in Colorado and elsewhere, are more susceptible. Any debilitating cause, as insufficient diet, hemorrhage, or anemia makes the individual less resisting. Another important point is that there is some degree of immunity in every individual, but probably not enough but what it may be overcome in the most resistant, and its being overcome depends mainly upon two factors: 1. The virulence of the tubercle bacilli, which varies very much at [illegible]t times. 2. The dose. In all of our laboratory experiments we find that in most infectious diseases a small number of bacteria may not give rise to infection when a considerable number may do so. So that people who live in air loaded with tuberculous sputa are much more likely to be infected than those who live in a climate where there is nothing of that kind. In short, we have the specific cause, the predisposition which is inherited to some extent and is developed by environment, and then the exciting cause; a person lives in an atmosphere loaded with dust, irritating the lungs; or there may have been some recent inflammatory condition of the mucous membrane which makes him prone to infection.

Dr. JAMES TYSON of Philadelphia—As one who has made a clinical trial of Dr. McFarland's antituberculin I may say a few words. I am not one of those who decry the effort to discover an antituberculin, a direct serum cure for this condition, although my own clinical results were absolutely negative, as I so reported to Dr. McFarland. They were necessarily so because of the very short time I was permitted to carry on the observations. But in that very short time I learned what seems to me to be a most serious difficulty in the determination of the clinical value of this remedy and the mode of administration. Until we can devise some other mode of administration than by the hypodermic syringe the difficulties will be almost insuperable in making a clinical trial of this remedy. With the urticaria and the extremely painful effects which attended the use of the remedy a short time in my wards, the patients were in a state of actual rebellion. The treatment is dreaded, so I was glad for some reasons that the serum gave out.

Dr. PAUL PAQUIN of St. Louis, Mo.—It would seem that tuberculosis is a mixed infection, and it has been thought useless for anyone to search for a specific remedy. That is probably true. I doubt if the world will ever find a remedy which will be called specific for any form of tuberculosis, whether pure or mixed. But we must recollect that, although this may not be possible, yet on that very line of argument and research it has been admitted here that certain cases of tuberculosis, perhaps all forms of at some stage or other, recover without the assistance of the doctor. Therefore, we must conclude that there exists in nature a power that can cure tuberculosis. What is that power? It is this very thing that we want to imitate in our researches. If a child recovers from diphtheria without medicine or in spite of medicine, nature gets the credit, and we exclude the case from the results obtained by antitoxin or attribute the result to antitoxin produced in the system itself. Now what the medical profession can do in diphtheria is to use antitoxin developed in the system of the horse instead of in the system of the patient suffering from diphtheria. It has been tried in tuberculosis, but with quite different results in many instances and for many reasons, chiefly because pulmonary tuberculosis is complicated with other germs besides tubercle bacilli which produce mixed toxins in the system.

One statement, which I think is not justified, is that we ought to wait seven or eight years before we come to a conclusion that any treatment of tuberculosis is rational. I do not think you will find a treatment which is specific in a hundred years. But I do think we ought to give credit to any kind of treatment which produces an improvement in the condition of the patient. What we want in clinical work is not, perhaps, laboratory work. The patient wants work on himself. He wants to be cured, and I think we are justified in giving the benefit of any measure which causes improvement to the patient and the profession.

I agree with Professor Klebs that the more we have of verification of clinical work by laboratory or experimental work, the better. At the same time, the medical profession has to confront a condition in tuberculosis and can not wait for experiments. When we do find beneficial results in clinics we have the right to give the profession the benefit of our experience.

Dr. MCFARLAND—To the gentleman who does not think the tubercle bacillus causes tuberculosis I would suggest that he make a few experiments and I think he will have no difficulty in convincing himself. In answer to the gentleman who says we have no serum treatment for any chronic disease, if such an argument had any weight and had been advanced a few years ago as to antitoxin, we would today have no antitoxin for diphtheria. It has been said that tuberculosis is a disease which gets well. Nobody doubts that. Laboratory men are directing their attention to the question of *how it gets well.* I have been surprised to see how much sympathy clinicians have with laboratory men. We ought to be the best of friends, and I hope that what we laboratory men are doing will in time be to your great advantage.

Dr. DE SCHWEINITZ—Dr. Cohen overlooked one point emphasized by Dr. McFarland and myself, namely, that tuberculin, as ordinarily prepared and used, is a solution of *some* of the products of the tubercle bacillus, but not of *all* of those products, as when the live germs instead of the dead are used. That has been my object and that of some others—to put to use *all* of those products or elements. The gentleman who does not believe in the infectiousness of tuberculosis says we ought to go back to fundamental physiologic principles. That is just what the laboratory men are working at.

Dr. ROCHESTER—There is not much to be said in reply. I think one or two things ought to have a little emphasis. One is that mal nutrition is one of the serious conditions associated with tuberculosis, and it ought to be fought as one of those things that interfere with the recovery of the patient. I do want to make a strong outcry against Dr. Herrick's heresy. He tries to underrate the work of laboratory men. I am not a laboratory man. I am a clinician. But during the last ten or fifteen years all the greatest work in medicine has been made through laboratories, and for clinicians to get up and say we ought not to pay attention to workers in laboratories is unpardonable in every way.

With regard to treatment, I reported a number of cases, and I feel that I ought to apologize to the Section for having reported upon one of the agents I used, namely, aseptolin. I think the profession ought not to use a remedy advertised as that was, and I wish to say that I used it at the request of a number of patients, and the results were as I stated them in the paper.

With regard to the remark of Dr. Tyson concerning the serum which he used—that the patients had a great deal of urticaria, and he had to stop the treatment on that account—the same thing occurred in my use of the Paquin antitubercle serum. It was not used long enough to say that it counteracted tuberculosis, for it produced too great pain. It produced actual dermatitis and swelling of the lymphatic glands, so that it had to be stopped. As to Vaughan's nuclein, some say it is not the proper thing to use; that it is unscientific. Now Vaughan's nuclein is not an antitoxin, but is intended to improve nutrition and the resisting power of the white corpuscles and blood serum. I have had results from nuclein which I have not had from any other remedy, and I shall continue to use it.

Dr. FLICK—It was necessary to be so very brief in my paper that I could only give results, and I fear I have been misunderstood in some of my statements. When I stated that we ought not to publish results as to cure in phthisis for five or six years, I meant cure, not improvement. In tabulating my cases I had that idea in mind. The use of iodoform and europhen in the treatment of tuberculosis is, I think, in line with the use of antituberculin, with a view to establishing immunity. I think this is the line along which a cure for tuberculosis will have to be found, for the very nature of the disease is such, as Dr. McFarland so well pointed out, that a direct cure is impossible. A cure can be found only along the line of immunity, and I believe that a cure along this line not only possible, but is within sight.

Dr. HERRICK of Cleveland—I had no intention of denouncing laboratory work, as might be inferred from the remarks of one of the speakers. But I find it difficult to accept all the conclusions from such work. I think free expression of opinion is justifiable. I am not able to connect the experiments with the results claimed.

Dr. BORLAND—In presenting my paper I did not and I do not underestimate the work of the bacteriologist. I did not wish to create that impression, for I value the bacteriologist as highly as any physician can value any specialist. My plea was mainly for those not engaged in bacteriologic work to give attention to the frequency of latent cases of tuberculosis, and thus save many valuable lives while laboratory experiments are going on. I would be the last man to decry experiments which would lead us to a means of securing immunity from tuberculosis, or to a specific cure for the disease. I have this to say about the medical world: We are twenty-five years behind the surgical world. The two great discoveries of the century are anesthesia and Lister's antisepsis. Now the surgeons are using antisepsis and the physician's are twenty-five years behind. We have external antisepsis. Why should we not have internal antisepsis?

Dr. S. SOLIS-COHEN of Philadelphia—Dr. Flick said that no case of tuberculosis should be reported until four to six years have elapsed, for no conclusion whatever can be drawn before the expiration of that length of time. There are a great many cases which get well under no treatment or any treatment apparently, and then get sick again, and that will go on indefinitely. For instance, a case of apparently acute tuberculosis came under my care eight years ago, in which the patient seemed to have recovered, but he returned to my office a few days ago nearly moribund. Now, that patient might have been reported as cured half a dozen times had he come under the care of different physicians in different attacks. The idea of prolonging life, however, is not to be overlooked, and I think Dr. Flick may give his treatment less credit than it deserves from that standpoint. No disease requires so much investigation to prove the effect of treatment as does tuberculosis. The response of the individual to different methods of treatment varies so greatly that each case must be an individual study, and for the indications presented by that case different methods of treatment will have to be adopted. There are, however, certain fundamental principles which we are all so familiar with that it would be superfluous to dwell upon them.

Dr. Rochester has well called attention to the importance of fresh air, exercise and diet. I for one should insist at this time on the necessity for the pneumatic treatment in the form proposed and carried out so well by Waldenberg and those who have followed in his footsteps. All the cases which I have reported as having recovered under this treatment have held their recovery up to this date, some of them fifteen years. I have seen some cases in the practice of my brother which have held their recovery twenty-five or thirty years. So that if there is any definite conclusion to be drawn from results in individual cases, I certainly think the results placed on record by reputable observers in favor of this measure prove that it is far superior to others.

I think Dr. McFarland has done well in calling our attention to the fact that tuberculin does not cause reaction in healthy animals, but only in animals already the subjects of tuberculosis. He has called attention also to the late occurrence of toxemic symptoms in cases of tuberculosis. Those two points taken together would seem to indicate that if there was the possibility of the production of an antitoxin through influence acting upon any susceptible subject whatever, it would be produced in patients in the long course of a chronic disease. Now, the immune animals, such as the ass and horse, from which antituberculin serums are being sought, do not react to tuberculin, and therefore whatever is taken from them is not of the same nature. The antitoxin does not bear the same relation as the antitoxin of tetanus and diphtheria. I believe in susceptibility to the disease, and that there are immune human beings just as there are immune animals. Whereas the guinea pig will almost invariably succumb if inoculated with tubercle bacilli, antitoxin or not, and the horse and the ass will rarely die, so we have among human beings some who are guinea pigs and some who are asses. Our treatment must be directed toward changing the guinea pigs into donkeys, building up this vital resistance which will prevent the person from reacting to the tubercle bacilli or tuberculin. Whatever method will have that effect, whether diet, exercise, massage, drugs or anything else, is what we are to use, and not go in a will-o'-the-wisp chase after specifics. Now, the drugs which have been mentioned can all be used and have been used. The journals, the dispensatories, the text-books, are filled with lists of drugs which have been used in tuberculosis. When the reports are reliable, and from good men, and the drugs are not harmful, let us try their remedies.

Dr. Rochester spoke of the use of certain remedies for fever; my own experience is that the best remedy for fever in chronic tuberculosis is rest, with an ice-bag over the heart—the method of Bremer. Dr. Vaughan in his early experiments with nuclein also sent me some samples, which I used on a number of patients at the hospital, with much satisfaction to myself, but with dissatisfaction to the patients. Several of them complained of intense pain from the injection. One of those patients I have placed in the list of recoveries. The other patients were improved and passed from under observation. I believe there is a scientific basis for the use of various nuclein products (some are better than others), in the building up of the vital powers of the patient. I do not look upon it as a specific against tuberculosis or any other disease. I wish to thank Dr. McFarland, too, for the opportunity he gave me to test his antituberculin serum. I saw it produce considerable mitigation of symptoms. The two deaths which occurred in my practice were certainly not due to the treatment, because at the time the treatment was begun we expected the patients to die at any minute. One of them lived three months, the other lived a shorter time. But these patients, too, complained of intense pain.

In conclusion, I would like the Section to look up the works of Waldenberg and the advantages of pneumatic measures in the treatment of tuberculosis. Do not search for specifics, but build up the patient's vital resistance, and use whatever drugs are necessary for the control of symptoms.

DISCUSSION ON GOUT.

Dr. James Tyson of Philadelphia—I want particularly to refer to the diagnosis of gout. I feel quite certain that fully one-half of the cases diagnosticated as gout are instances of erroneous diagnosis. One of the conditions most frequently mistaken for gout is that peculiar deformity of the knuckles known as Heberden's nodosities. Heberden's nodosities do not mean gout. Heberden stated that they were not gout. But they are constantly said to be gout by practitioners. The nodes have not the same composition as those of gout. I agree with Dr. Stockton, that uric acid in the urine is by no means always an evidence of gout. Indeed, the man who has uric acid sediment will not have gout, and the man who has gout will not have such sediment—I mean in the shape of calculi. How shall we know gout? By the occurrence of two or three things: 1. An attack of true podagra. 2. The presence of tophi in the eyelids, etc. 3. Heredity. If you find a person with these manifestations, whose father or grandfather was undoubtedly gouty, you may again be justified in concluding that these conditions are gouty. It seems to me one or the other of these three facts must be found before you can say the case is gouty and hold to your diagnosis.

There is a point with regard to treatment which I believe has not been alluded to, namely, the continuous use of alkaline mineral waters between the attacks of gout. Gout can not be cured. Gout may, in the course of years, pass away. There must be a constant attempt to keep the symptoms in abeyance. It is treated with salicylates better than with any other remedy, but we can not do away with the continuous use of alkaline mineral waters, especially the foreign vichy. Citrate of potassium is a good artificial substitute. Of course diet is important. I must confess to using salicylate of sodium, also salicylic acid and sodium bicarbonate. I can support Dr. Wood in the statement that salicylate of strontium is easier on the stomach.

Dr. D. L. Rochester of Buffalo, N. Y.—The very scientific papers of Dr. Hutchinson and Dr. Stockton impress one with the idea that we have two distinct conditions, one of gout and one of uric acid. These two papers have pointed out the ways in which we are to examine our patient in order to treat them properly, and I simply rise to emphasize the points made in them.

Dr. Carpenter of Pennsylvania—For thirty years I have treated gout principally on the basis of hints which I got from Prof. George B. Wood, whose lectures I had the pleasure of hearing when a young man. I have noticed during this discussion, that no allusion has been made to one important fact with regard to gout, and that is the periodicity of its attacks. Years ago I noticed that it was likely to recur once or twice a year—spring and fall. There are other ways in which gout manifests itself periodically, one being gouty eczema of acute variety. I watched such a case, that of a worthy lady, for about sixteen years, who had attacks of true podagra or of eczema about once a year. The last year of her life she had no attack, and that suppressed outbreak of stored-up poison was followed in a few months by heart and other troubles and she died.

Having seen periodic manifestations of gout in the joints and in the skin, there is a third variety which I have been convinced of many years, namely, hay fever. The exciting cause may be some germ or irritant from the vegetable kingdom, but I believe the large majority of the people who are subject to hay fever are gouty. This question of the periodicity of gout not having been alluded to, I thought it desirable to have it spread upon the records as an important point in diagnosis.

Dr. H. A. West of Galveston, Texas—I was very forcibly impressed by the remark of Dr. Wood as to the comparatively few cases of true gout which had come under his observation. That has not been my experience. I have seen a good many cases of genuine gout. With regard to the etiology, I have seen cases in which I could attribute the gout to nothing else than the excessive use of nitrogenous food, especially eggs. I have observed gout from the same cause, excessive use of nitrogenous food, in butchers, and also in cooks. The necessity for regulating the diet has been fully insisted upon.

Dr. Woods Hutchinson of Buffalo, N. Y.—Exercise, exercise, and again exercise—training your patients as if it were the intention to get them into trim to run a hundred yards in ten seconds; get them up to the highest possible pitch of human development! On one point I differ, namely, the distinction and absolute separation between gout and lithemia and intestinal toxemia. One thing which Dr. Wood said I cordially agree with, that is that our knowledge of gout consists largely of what I think he called "[illegible]rumbling expectations." We know little abou[illegible] thi[illegible] [illegible]all have to qualify my statement that we [illegible] [illegible]umatism except that two-thirds of it is gout, by the further statement that we know little about that. But we are in the way to learn something. One thing which we do not know is whether this peculiar ancestral reversion on the part of the metabolism cells begins in the muscle cells, or liver cells, or cells lining the alimentary tract, or the kidney. I think it unquestionably begins, in many cases, in the intestinal tract.

DISCUSSION ON PAPER OF DR. D. L. ROCHESTER, OF BUFFALO, ON "THE PROGNOSIS AND THERAPEUTIC INDICATIONS IN HEART DISEASE."

(*Vide* Journal, Vol. xxviii, p. 1207.)

Dr. J. B. Herrick of Chicago—I rise to say a word for one method of treatment which has passed somewhat out of fashion—venesection. The benefit of this method has been brought home to me in three cases of cardiac dilatation where the dilatation was due apparently to fibrous myocarditis. The patients entered the hospital with extreme dyspnea, amounting to orthopnea, extreme cyanosis, edema, with feeble arhythmic pulse, feeble heart sounds, and with systolic murmurs believed to be connected with the mitral and tricuspid valves. In these cases, believing that stimulation of the heart would not do as much good as relief from the work which the heart was required to do, abstraction of eight to sixteen ounces of blood was practiced, and in all three of these cases with the most gratifying results, in one temporary, in the other two more permanent. So I would speak favorably of treatment by venesection in certain selected cases of cardiac dilatation.

Dr. H. A. West of Galveston, Texas—I would mention two factors in connection with aortic incompetency that are not always recognized, and not always considered as affecting the condition of the heart and its muscle. One of these is the continued hydrostatic pressure of the column of blood acting through the incompetent aortic valve upon the cavity of the left ventricle—a very important factor in producing dilatation. The other factor is the local disturbance of the circulation in the heart itself, depending upon the mechanical interference with the entrance of blood into the heart through the coronary arteries in consequence of the incompetent valve. These two factors are exceedingly important. They point to the rationale of treatment by rest as a means of decreasing the hydrostatic pressure; hence, also, the value of treatment by vene section, decreasing the volume of blood. This, taken with rest, meets very important indications indeed. The disturbance of the nutrition, the degeneration of the heart muscle depending upon the disturbance of the circulation in the coronary arteries is an exceedingly important factor and one whose influence it is frequently difficult to forsee. I have no doubt that it often explains the fatal result in cases that otherwise would be difficult to explain.

Dr. J. B. Marvin of Louisville, Ky.—This paper contains lessons which many of us need to bear in mind. Preceding prognosis should come diagnosis. Certainly the time has passed when a man bases a prognosis on the mere presence of a murmur heard over the cardiac area. As the author has well stated, there are other factors to be taken into consideration besides the murmur, such as the condition of the peripheral circulation, of the arterial system, of the heart muscle itself—and of these three factors certainly the last is most important. A murmur may mean very little, but if it is taken into consideration with the other two factors it may mean a good deal. Another point which might be mentioned in connection with this paper is the fact that there are cases of what may be called acute dilatation, occurring, as indicated by Dr. Osler, in persons of middle age, and which yields most readily and most happily to rest in bed, to dietetic management, and to the Schott treatment. Other cases are more chronic, occur in older people, older not as we measure time necessarily, but older with regard to the integrity of the heart muscle, where there may have been valvular trouble and compensatory hypertrophy now followed by acute dilatation. Such cases do not give brilliant results from any method of treatment.

In therapeutics I must add one or two other things to those named by the author, for while in hospital practice those do sometimes yield most brilliant results, yet I must ask in addition for strychnia. I do not care so much for digitalis, but I would greatly dislike to be called to treat a case of cardiac trouble without strychnia. And I am satisfied that many follow our homeopathic friends and give too small doses. I want an appreciable dose, and I prefer to give it hypodermically, with increasing amount, starting with one-twentieth of a grain. I have yet to see a toxic influence from strychnia given in increasing doses by injection.

Dr. J. N. Upshur of Richmond, Va.—I rise to endorse what the gentleman has just said with regard to strychnia. To me it is *par excellence* the remedy and, as the gentleman has said, in full doses. It is the most honest of all remedies, giving fair warning of its ill results when its physiologic effects have been produced. To strychnia I would add one other remedy, nitroglycerin. It diminishes the resistance in the arterial system and enables the strychnia to stimulate the heart in a way to get the best results.

Dr. S. Solis Cohen of Philadelphia—As I understand Dr. Rochester's paper, his purpose was to lay down the principal lines of treatment rather than enumerate all the remedies which might be used. I would go farther than the gentleman who has just suggested nitroglycerin. We might speak of spartein, of strophanthus, etc.; but what I would like to emphasize once more is the great satisfaction I have had with the method spoken of by Dr. Herrick, venesection. I think we of the younger generation, who were not brought up to bleed, have been entirely too much afraid of it. During the last ten years I have been resorting more and more to the use of the bistoury on proper occasions, and I am becoming more and more convinced that those of our predecessors who advocated venesection for relief of the heart, and for control of inflammations, knew what they were talking about. The advantage of the procedure was strikingly illustrated in a recent case in the Philadelphia Hospital. The resident physicians who have charge of my patients know that as soon as they have a proper case they are to bleed, without waiting for me. A patient with fibrous senile heart came into the hospital, cyanosed. As there was no time to send for me, the resident physician opened a vein, took away about sixteen ounces of blood, and the result was that the woman, who had come into the hospital almost *in articulo mortis*, rapidly improved and has been discharged. She is not well of her fundamental heart disease, but has been relieved from imminent danger of death and promises to live a number of years under proper hygienic management. If nothing else should come out of this discussion except the renewal of testimony in favor of the advantage of relieving the weak heart by taking out of the system blood loaded with toxins which can do no good to the patient, but only obstructs the free flow of the circulation, I hope at least that much will come.

Dr. Wainwright of Kansas City, Mo.—I wish to say one word with reference to the prophylactic treatment of cardiac lesions. I believe the profession is largely responsible for a great many valvular lesions because of lack of knowledge of what is now held to be causative of such lesions, and failure to diagnosticate their presence during the inflammatory stage. According to authority, 50 per cent. of all valvular lesions are accompanied in the beginning by inflammatory rheumatism, and I believe that if the conscientious physician would study the heart in all cases of inflammatory rheumatism he would be able to prevent disease of the valves. I speak for rest in prophylactic treatment. Rest will prevent those extensive changes in the valves which we are now frequently called upon to treat. When it comes to the treatment of existing valvular lesions, it seems to me physicians are too apt to treat the condition before treatment is indicated. Take the average practitioner throughout the country, when he hears a cardiac murmur he thinks it is an indication for digitalis or strophanthus. He interferes with the laws of nature when nature is compensating perfectly for that lesion, and by his interference he disturbs the compensation and brings about dilatation.

Dr. J. F. Jenkins of Michigan—I have heard a good many things attributed to the neglect of the medical profession, but this is the first time that I have heard of the medical profession making patients have heart disease. In fact I do not think there is a case of rheumatic endocarditis in which the doctor has had anything to do with inducing the disease. In all probability the disease was there before the doctor saw the case. In fact, cardiac disease is one of the commonest affections produced by rheumatism and I should dislike to see the physician accused of being the cause of it.

Dr. Rochester—As Dr. Cohen said, the paper was devoted to the prognosis and therapeutic indications rather than to an enumeration of all the drugs. The therapeutic indications which I spoke of were the relief of peripheral obstruction and improvement of the musculature of the heart and arteries. The various methods by which this might be secured were not entirely gone into, but merely touched upon. I am glad venesection has been mentioned, for I am one of the younger members of the profession who practice it when the time comes for it. The indications for venesection pertain to failure of the right heart. I did not speak of disease of the arterioles of the heart especially, but included those with the arterioles of the rest of the body. The use of strychnia and nux vomica is one of the hobbies of the reader. A great many physicians are frightened when I tell them that I have frequently given a drachm of tincture of nux vomica at a dose, three times a day. Strychnia I have given in the same proportion, after gradually working up to that dose. The use of strychnia and nitroglycerin alternately simply produces the same condition which we can bring about by baths and exercise—dilatation of the arterioles, etc. If we can bring about these effects without introducing poisons into the body, we can do much better for our patients, and I want to enter a strong plea here for the employment of exercises, such as are used in the Nauheim treatment, and for the use of baths whether they do or do not include salt or carbonic acid. Use baths, rubbing of the skin, and all measures which we can without drugs, and when these fail we can fall back on drugs.

DISCUSSION ON DR. F. A. PACKARD'S PAPER "TRICHINOSIS IN THE UNITED STATES."

(*Vide* JOURNAL, page 59.)

Dr. CHARLES STOCKTON of Buffalo, N. Y.—I agree that this disease is often overlooked. I feel convinced that I have myself overlooked it because after having once recognized it I could look back with a more or less clear vision upon previous cases and come to the conclusion that I had overlooked it several times. I think the point to which Dr. Packard has called attention should be borne in mind, and I hope he will allow me to add to this important sign those of sweating and edema. It seems to me that if we add these two signs to the other two, it will constitute a picture which can not well be overlooked.

Dr. A. P. OHLMACHER of Cleveland, Ohio—I wish the author had added something about treatment. The trichina is killed by lime salt. Now, if in some way lime salt could be got into the blood, would it not get rid of the trichina?

Dr. PACKARD—I have mentioned sweating. I would put with it as of equal value, thirst. With regard to treatment, this man got salicylate of soda during his stay in the hospital, principally for the reason that it was cheap and in the doses given it was harmless. The only other treatment which he received was in the way of cathartics, calomel, salines, and an occasional dose of castor oil. With regard to giving lime, the trouble is that it is too late. As soon as the trichina becomes encapsulated it can do no harm save by being eaten by the rat or pig.

DISCUSSION ON PAPER OF DR. S. SOLIS-COHEN, "THE TREATMENT OF EXOPHTHALMIC GOITER AND OTHER VASOMOTOR ATAXIAS."

(*Vide* JOURNAL, page 65.)

Dr. C. F. HOOVER of Cleveland, Ohio—I may mention the case of a woman with marked scleroderma, bronzing of the skin, leathery binding feeling of the hand, inability to close the hand on account of the scleroderma, cessation of menstruation, irregular heart. There was no sweating, no exophthalmus. Within four or five days after commencing thyroid feeding the cardiac rhythm was perfectly restored; in the course of three or four weeks menstruation returned, and I was astonished to find that the scleroderma and bronzing entirely disappeared.

Dr. S. SOLIS COHEN—I do not know in what way the thymus gland administered in these cases acts. The thymus and the adrenal extracts should be given tentatively. I get the best commercial preparation which I can find. I give tabloids of five grains each, beginning with one a day and increasing until in some cases I get up to six a day. In other words, testing the susceptibility of the patient in each case, first dividing the one tabloid in three parts, giving the three parts in the course of the day, and finally in some cases going up to two tabloids three times a day. Dr. Owen has used much larger doses of thymus, but I have begun with the smallest dose, and in some instances have run up to 30 grains a day, or as far as I think the patient will stand it, both of the thymus and adrenal extract.

Dr. HERRICK of Cleveland, asked whether other medicines were given, and Dr. Solis-Cohen replied in the negative.

DISCUSSION ON PAPER OF DR. HENRY BEATES, "THE USE OF DIGITALIN WITH REFERENCE TO DOSE."

(*Vide* JOURNAL, Vol. XXVIII, p. 1209.)

Dr. HERRICK of Cleveland, Ohio—We are coming to the region of therapeutic agents for the treatment of disease, a region of great skepticism, great doubt with regard to specifics and special agents. This paper is valuable for what it has given. I think, however, that there are some problems involved in the administration of digitalin. As the author has intimated, its action is through the pneumogastric nerve, and it is applicable to a certain class of cases. Would the Doctor administer digitalin in inflammations of the heart? I think the common custom among physicians is to give digitalis in any heart disease. Heart disease: digitalis! I would put in a word of caution; never give digitalis in inflammation of the heart. But in other conditions, through the pneumogastric nerve, I think we may somewhat limit the region of its activity.

Dr. BEATES—As to whether digitalis should be used in inflammation of the heart, if the Doctor means simple inflammation or conditions in which there is active inflammation of the heart, it certainly should not. If, however, he includes in the term inflammation the consequences of the acute condition after the latter has subsided, I would say that I myself would not then use *digitalis* because it is complex; I would not use *every* digitalin, because they are so different, but I would use *this* digitalin. In acute inflammations of the heart the drug is certainly contraindicated, but in the results of the acute forms of inflammation of the heart I would certainly urge this particular digitalin as a therapeutic measure.

DISCUSSION ON PAPER OF DR. J. M. ANDERS OF PHILADELPHIA, "MYXEDEMA WITH REPORT OF TWO CASES."

(*Vide* JOURNAL, page 63.)

Dr. RUSSELL—A mistake in diagnosis is frequently made, even in pronounced cases. In the Howard Hospital a very marked case in all its characteristics had been treated, as long as a year, for chronic gastric catarrh as well as liver trouble instead. A knowledge of the clinical features of the disease is essential to diagnosis, a fact which should be better known to the profession. Within two years I have seen a case very similar to one of Dr. Anders. The patient was a woman who had been treated about two years for parenchymatous nephritis. The urinary changes were markedly pronounced, but at no time were there cardiac changes or edema, and it was only as a tentative treatment that thyroid was tried, not so much with the idea that there was a myxedematous complication. The result was eminently satisfactory, for the urine has been normal for a period of eighteen months. The case at the Howard Hospital rapidly improved under thyroid, but at no time were we able to administer more than five grains of thyroid extract three times a day. Within seven weeks the patient lost some thirty pounds, and has been in every possible way benefited.

SELECTIONS.

On the Question of the Removal of the Second Ovary in Ovariotomy.—Dr. D. Thomson relates his experience in exemplification of the above question, saying: I firmly believe there can be no fixed defined and inalienable rule in these cases. I remember years ago removing a cystic ovary from a young woman, unmarried, leaving the other, which was enlarged and tender. She made an excellent recovery, but when well enough to be discharged and get about she began to complain of symptoms pointing to the ovary which was left behind, and she was repeatedly sent to me to know if she had not another tumor coming and if it was not advisable to have another operation. I saw no reason for it and refused, and this young woman is now perfectly well. There was pain and tenderness, but I did not consider these sufficient to justify another operation. One can not avoid the feeling that in this case the second ovary might have been removed had I been strongly impressed with the need for it at the time of operation. We might have had this case to swell the number of double removals, and the tender condition and enlargement would have been employed as arguments in justification. I know of a case of cyst of the broad ligament which I was about to remove five years ago, but which, owing to the very alarming symptoms occasioned by the anesthetic, I was obliged to desist from doing when just about to enucleate it. The operation was immediately stopped and the abdomen closed. From that day to this the cyst has not been enlarged; indeed, it underwent some degree of diminution. I have seen the patient at intervals of a few months since and she has continued very comfortable and able to attend to her business. During the time I had the patient under observation previous to the operation the cyst had been increasing, and I only decided to operate because of the disturbance and pain it was causing in its neighborhood, as well as rendering the woman unfit for her duties and giving her great general discomfort. Its presence does not now cause these symptoms in anything like the same degree, and, as I have already said, she attends to her daily duties, which are of an arduous kind. Why the cyst ceased to increase is another question, but it may have been *in some measure* due to the fact that I made her rest absolutely for six months. I accidentally discovered a cyst of the ovary, when attending a woman four years ago for another matter. It had not increased when I last attended her a few months ago, and she at present suffers only a little from it. She does not know of its existence. Why should she so long as it gives such slight trouble and she is quite able for her duties? She has had two children since I discovered the cyst, and if it has remained *in statu quo* for four years (and perhaps for four years previous to that) may it not remain so for four, or even fourteen, more? I may also instance the case of a young married woman in whom a tumor (cystic) of one ovary has existed to my knowledge for years. It has at times caused a good deal of suffering, and on one occasion I almost decided to remove it. Several months of absolute rest, however, with some treatment, helped her greatly, and she has been able to attend to her household affairs with a considerably greater degree of comfort than previously. I have known of the existence of this cyst for six or seven years, and it does not increase.

The advocates for removal may say that it would be better to remove the organ than for the woman to undergo the trouble, anxiety and suffering of a second operation, with its consequent risk and expense. The risk is small now, thanks to progress made in surgery during the last quarter of a century, but there is a risk, and it ought to be avoided, to say nothing of the other concomitants of an operation. But if there is a reasonable hope that the ovary may not get worse or may recover, I think the woman, especially if a young one, ought to have a chance and the ovary should be left, and I think it may be fairly said that the cases cited show that ovaries to some extent diseased may be left sometimes with a very fair prospect that they may not only not cause increased trouble in the future, but that they may remain stationary even recover. If, then, some diseased conditions of the ovaries remain quiescent for years, improve and even get well, we ought not too hastily to conclude that operative interference is necessary, but should keep our patients under observation and treatment. I am confident that some operations may be avoided by this plan, and the subjects of the disease be enabled to pursue their daily duties with comfort.—London *Lancet*.

Clinical Experience with Formaldehyde.—In the *New York Medical Journal*, January, Dr. M. S. Alexander states that he has used this drug in whooping-cough and numerous other conditions with gratifying results. It should be remembered that formalin solution has no caustic properties. It does not hurt the instruments, not even as much as blunting the edge of the cutting instruments. The same solution was always used for irrigation when the dressing of wounds was changed; this too gave such satisfaction, that it has been altogether used in a great many operations. "I have used it altogether in my practice for almost a year. I have no more need for corrosive sublimate or carbolic acid. I wish to emphasize the fact that formalin does not attack metals at all. It is best adapted for antiseptic solutions (1 to 500) in which to keep instruments. I have had no alarming results with formalin locally; indeed, in cases of chancroid and chancre, the pure (40 per cent.) was applied without any bad results other than pain, with the benefit of rapidly healing the ulcers with a single application. I have never failed to get better results from it in skin troubles than from any other remedy. I use it by blowing it into the skin by a compressed air sprayer.

"I have cured an old case of pruritus vulvæ that had been treated by many different specialists for three years. In all affections when any of the old disinfectants, such as carbolic acid, corrosive sublimate and many others cause trouble by irritation and poison if not applied very carefully, this is all lost sight of and overcome by the happy and safe use of formalin.

"Cases of whooping cough are treated successfully by spraying with an atomizer three times daily, using a 1 per cent. solution for fifteen minutes. I have never had an opportunity to use it in scarlet fever, but no doubt it would prove of great utility in all infectious and contagious diseases for the following reasons: 1. It has extraordinarily active antiseptic power, similar to that of corrosive sublimate; 2. It attacks only the substances of the contagious material, leaving unattacked the articles treated, whether organic or inorganic; 3. It is very readily employed under all circumstances either as a liquid or as a gas. Another marked advantage of the vapor of formalin is that its specific gravity closely approximates that of air, so that there is no difficulty in keeping the atmosphere of an inclosed space uniformly impregnated. For this reason it suggested itself to me as a happy remedy in catarrhal troubles. In hay fever it surpasses all other agents known. I use a 0.5 per cent. solution as a spray, and by taking a drachm phial and filling it with a 2 per cent. solution and allowing the patient to inhale the fumes, I can come as near curing the most obstinate forms of catarrhal troubles as by all other means known. The fumes seem to reach portions that can not be penetrated by the spray or douche. I treated fifteen cases of infantile diarrhea with only one death. Half a grain to a grain and a quarter at a dose every two hours. In conclusion I will say that I can clinically recommend formalin as being in the lead among intestinal antiseptics, and far superior to all other agents known in its sphere."

PRACTICAL NOTES.

The Favorable Effect of Hydrastis Canadensis in Bronchitis is announced by Saenger (*Cbl. f. In. Med.* 17, 1897). The cough diminishes, expectoration becomes easier, secretions lose their putridity, while it is superior to opium or morphin in its soothing effect in such cases and even in phthisis, as its effect is more powerful and lasts longer.—*Nouv. Remèdes*, July 8.

Massive Injections of Artificial Serum in Extensive Burns have been found remarkably beneficial in combination with antiseptic and soothing dressings, by Prof. Tommaselli of Palermo. Two observations are described in the *Semaine Méd.* of July 21. In one case more than two-thirds of the front of the body was burned. The first day 250 grams were injected, increasing to 500 the fourth and continuing this to the nineteenth day.

Formol in Dental Surgery.—Didsbury announces in the *Journ. de Méd. de Paris* of July 18, that it has been his experience that formol applied at once to the cavity, when the pulp of a tooth is removed, and hermetically enclosed, renders the extraction of the nerve unnecessary. Ten cases in twelve proved absolutely successful. The pain is severe for four or five minutes but then passes away. He also finds formol efficient in deodorizing carious cavities.

The Omentum Used to Close Perforation in the Stomach from Gastric Ulcers.—Prof. H. Braun has thus treated two cases with success, and recommends the method when the tissues are too friable to suture alone. In one case the wall was perforated and extremely thin; to cover it he drew up a thick fold of the large omentum and sutured it over the spot, before commencing his gastro-enterostomy. The operation was completely successful and the woman is in good health now, three and one-half years since. Bennett also reports using an omental plug to close an otherwise intractable opening in the stomach. —*Cbl. f. Chir.*, July 10.

Iodoformed Ether in Catarrhal Metritis.—Doleris recommends touching the cervical cavity with a cotton pad dipped in iodoformed ether. The ether causes the muscles of the cervix to contract and empties the glands of their infected mucus, while the iodoform disinfects. He has been very successful with this method, the only one which completely evacuates the glands of their contents.—*Nouv. Remèdes*, July 8.

Thyroid Medication in Fractures.—G. Gauthier has found that fractures in which consolidation does not promptly occur, can be favorably influenced by administering thyroid extract. He reports two cases thus treated, and states that the successful consolidation took place rapidly and was complete, after the failure of other treatments, for 110 days in one case and three months in the other. He urges others to experiment in the same line, which was indicated by the success of the thyroid extracts in the development of bony tissue in myxedema.—*Semaine Med.*, July 14.

Large Doses of Ether in Uremic Dyspnea.—Lemoine and Gallois report great benefit derived in acute nephritis, congestion, etc. (except where the uremia is due to arteriosclerosis), from hour to hour doses of 2 to 3 teaspoons of ether in sweetened water, or alternating it every third hour with 2 to 3 cm. injected subcutaneously. In some cases 300 grams *pro die* were administered without inconveniences. Copious diuresis was induced, the pulse became stronger and quieter, the respiration deeper and fuller.—*Wien. klin. Woch.*, July 8.

Substitute for a Suspensory.—After shaving and disinfecting the skin, the assistant seizes the lower part of the scrotum, the patient in the decubitus dorsal, and draws it up tight, the testes settling down close to the inguinal rings. Around the scrotal pedicle thus formed between the hand of the assistant and the testes, a strip of very adhesive sparadrap is applied, 3 cm. wide by 75 long, compressing the scrotum to the size of a thumb in a horizontal ring, two other strips are applied over it and three more just above and half overlapping it. In acute gonorrhea, with or without epididymitis, this compressing ring will be found more effective than a suspensory, especially if the patient keeps his bed. After the first half hour it ceases to be felt. As the tumefaction subsides, additional circles can be applied above it.—K. Gerson, Berlin, *Semaine Méd.*, July 21.

Cardiac Syncope in Great Altitudes.—A correspondent of the London *Lancet*, in explanation of the mountaineering accidents in Switzerland, eliminates as causes, at least among the chief, loss of balance, misplaced footing and recklessness. He even turns somewhat coldly from the phrase, "accident due to misadventure," as explaining the disasters expected to befall the foolhardy climbers. He alludes to the many grave considerations which loom up in such enterprises as the Jungfrau Railway with a height of 12,000 feet above the sea level, and refers as well to a congress of the Swiss faculty held at Arona, where an impressive warning was given to travelers "not to venture on rapid ascents above the snow line without a physician's sanction."

An Unusual Complication of Lithotrity.—White (*Lancet*, July 17) reports the case of a man, 52 years old, who came under observation for the removal of a vesical calculus of many years' standing. In the course of the operation of crushing the lithotrite jammed, with the blades three-fourths of an inch apart. A surgical instrument-maker was sent for, but he was unable to liberate the blades, which were too far apart to allow of the withdrawal of the instrument. Suprapubic cystotomy was therefore performed, and after the removal of the calculus the blades of the lithotrite were protruded through the wound, placed in a vice and pressed together until the female blade fractured. The male blade could now be driven home and the instrument was removed. Had the vice failed preparations were made to file through the projecting end of the male blade. The bladder could not be distended, owing to the presence of the lithotrite in the urethra, but the use of a large rectal bag removed all difficulty of reaching the bladder. The stone, with the crushed débris, weighed an ounce and a half and was a typical calcium oxalate calculus. The lithotrite was an old one that had seen much service.

Occluded Vermiform Appendix.—Dr. Arthur Latham exhibited before the Pathological Society of London a vermiform appendix which had been removed from a man, aged 46 years, who had died from lobar pneumonia. There was no history of any symptoms connected with the appendix having occurred during life. The specimen was nine centimeters long and considerably dilated throughout its course. There was no comunication between the appendix and the cecum, the lumen of the former having been obliterated at its junction with the cecum by adhesive enteritis. The appendix was completely filled with numerous small bodies which had the appearance of ova. The largest of these was about the size of a dried pea. On microscopic section they showed an irregular fibrinous structure, which in places was somewhat laminated. They did not give a mucin reaction and stained readily with acid dyes. The wall of the appendix was irregularly honeycombed owing to pressure exerted by the above bodies. It was further thickened, and on section showed loss of mucous membrane and also of lymphoid tissue, possibly due to membranous enteritis. He had been unable to find any similar case on record.—London *Lancet.*

Radiant Heat in Ulcers of the Leg.—Dr. Colleville, professor in the Rheims School of Medicine, treats ulcer of the leg by exposure to heat without any very elaborate apparatus. All that is required is a square plate of metal which will stand heating, and a Bunsen burner. The blue flame of the latter impinges on the metal so as to bring it to a dull red heat, and the ulcer is exposed to the action of this at a distance of about ten inches, the rest of the limb being protected by bandages. The temperature is about 45 degrees C., which is easily borne, and the flame is regulated so as to maintain this temperature at the wound during the whole of the sitting, which lasts for from twenty minutes to an hour. At the conclusion the surface is found to be glazed over, large granulations being visible through the semitransparent coating. It is best to leave the ulcer exposed to the air for some time, and when it is dressed care should be taken that its surface is not touched by the aseptic gauze or other material used, Some improvement is generally experienced by the patient even after the first sitting, and cicatrization is completed in from five to twenty-five applications. In the latter sittings, when the ulcer is nearly healed, a more moderate degree of heat may be employed. Where gas is not available the heat of the sun or that of a fire may be utilized. Dr. Colleville attributes the beneficial effect of this method to the combined action of heat, light and ventilation.

A New Method of Treating General Suppurative Peritonitis.—Finney (Johns Hopkins Hospital *Bulletin*, July) reports five cases of general suppurative peritonitis (including one of typhoid perforation) successfully treated by a new method. The same procedure was followed in a sixth case, and although the patient was at the same time *in extremis*, life was prolonged for thirty-six hours. It is not claimed that the principle involved in the operation is a new one but only that the manner of its application is original. The operation consists first in a sufficiently long incision to admit of easy access to all parts of the peritoneal cavity. Next the coils of small intestine are quickly withdrawn, beginning wi [illegible] worst

All or as much of the small intestines as is necessary is removed and placed outside of the abdomen and covered with warm gauze or towels. Then the peritoneal cavity is thoroughly and systematically wiped out with large pledgets of gauze wrung out of hot salt solution, particular attention being paid to the pelvic portion. In some cases it may be well in addition to flush out the cavity with warm salt solution, but this is rarely necessary. Next the small intestine should be systematically examined loop by loop while still outside the abdomen and rendered macroscopically clean by wiping with gauze compresses wrung out of hot salt solution. It is necessary to wipe with considerable force at times in order to remove adherent flakes of partly organized lymph. This should be done thoroughly and conscientiously, as upon it depends in a large measure the success of the operation. The cleansing process is facilitated and the shock of the operation is lessened if the wiping of the intestinal coils is carried on under a constant irrigation of warm salt solution. After being cleansed macroscopically of all foreign material, pus, feces, lymph, etc., the intestines should be replaced in the abdomen, the worst or sutured coil being the last or most superficial, in order that it may be the better drained by being packed about with gauze if necessary. The abdominal wound is then tightly closed, just enough room being left between two sutures for the gauze drain. If there are any evidences of distension or pain the Paquelin cautery should be thoroughly applied to the abdomen and the bowels moved early by calomel in broken doses, followed by salts and a turpentine enema. An experimental study by Elting and Calvert (Johns Hopkins Hospital *Bulletin*, July) of perforative peritonitis submitted to the foregoing treatment showed that mere mechanical irritation of the peritoneal surfaces will lead to the formation of adhesions; that peritonitis in dogs caused by a perforation of the intestine is of an intensely hemorrhagic character and if left to itself rapidly proves fatal; that generalized peritonitis of this character in dogs can be cured as late as six and a half hours after the operation by the cleansing method described, and that mere closure of the perforation, without this cleansing operation will rarely if ever cure a case of generalized peritonitis in dogs.

The Sclerogenic Treatment of Tuberculous Affections.—Sematzky has been carefully investigating this subject, which was first introduced by Lannelongue of Paris in 1891. His method of treatment consists in the deep injections of the chlorid of zinc around the diseased part. During the years 1893-96 thirty cases of every variety of tuberculous disease were thus treated by him. From these, however, ten, the observation of which could not sufficiently be carried out, must be deducted. Of the remaining twenty, in ten cases highly satisfactory results were obtained, in seven fairly good ones, and only in three no effect whatever resulted. It is noteworthy that the presence of pulmonary tuberculosis greatly reduces the chance for this local treatment. The solution used by Dr. Sematzky for these injections was of 1 in 10 strength, and according to the age of the patient, from seven to ten drops were injected in a number of places (from twelve to twenty) around the periphery of the affected area. As regards the form and technique of the operation he, on the whole, followed the rules laid down by Professor Lannelongue in his first detailed communication on the subject to the Academy of Sciences (July 7, 1891). In some respects, however, he was forced by experience to modify them. For instance: 1. As to the time of repeating the injection, he did not wait as long as three weeks, as was recommended by Professor Lannelongue, but performed a second injection as early as on the seventh or even third day after the first injection, being guided by the indication if the pains did not cease within that period. 2. The administration of anesthetics he regards as quite unnecessary in adults, and even in children the operation can be easily done without them, since the pain is merely that associated with all subcutaneous injections; indeed, they were slight and fugitive in character in almost all cases of his observation. 3. By observing rigid aseptic precautions, the appearance of swelling, redness and signs of any inflammatory reaction, as described by Professor Lannelongue, taking place in the vicinity of the injected area are avoided. Dr. Sematzky was accordingly able to employ an immobile dressing immediately after the injection, which proved to be exceedingly useful. The skin was first covered with collodium elasticum or traumaticum, and a solution of silicate of potash served for the immobile bandage. Professor Lannelongue's statement that this mode of treatment has no effect, or little, on the general health, we find so far fully confirmed by Dr. Sematzky's record, but in the matter of the action of chlorid of zinc on tuberculous tissues he greatly differs from the first-named observer's opinion. He acknowledges that it gives rise to a condition of sclerosis, but what is fatal to the existence, or at any rate paralyzing to the activity, of the bacillus is, according to the writer, the great antiseptic power of which that drug is possessed. At the conclusion, he remarks that this method of treatment, on account of its being very simple and easily accessible to every practitioner, deserves far more attention than it has as yet received, and if employed at an early period, and especially while the formation of granulations sets in, good results will always follow.—London *Lancet*.

Pathology of Morvan's Disease.—In view of the recent death of Dr. Morvan, the following interesting review of the latest status of pathology of the disease that bears his name will be opportune. The Paris letter-writer of the *Medical News* states, that Marinesco and Jeanselme have made public their researches on that disease. He says that it has until recently been the custom in France, to always regard the disease as an abortive, incomplete, atypical form of syringomyelia. In the East, especially at Constantinople, the similarity of the symptoms ascribed to Morvan's disease, especially its completely anesthetic mutilating panaris, and the fact that Morvan, in a country district of less than 50,000 inhabitants, found some fourteen cases of it, led them to suspect indigenous but deteriorated forms of leprosy. There, where leprosy is so common and its varying characters so familiar, the thought does not seem so strange as it would farther West. Not long ago, Zambuca of Constantinople found, in what was symptomatically a typical case of Morvan's disease, the cavity in the cord which would be expected in syringomyelia, but he found, in addition, in the broken-down material of the cavity, Hansen's lepra bacillus. This attracted a great deal of attention and even led to some doubts as to the etiology of even the more typical cases of syringomyelia.

Marinesco reported the careful autopsy of a typical case of Morvan's disease on which Charcot, in 1890, based one of his clinics, while Jeanselme reported the necropsies of two cases of the disease made in Bretagne, where Morvan's original study of the disease was made. Marinesco found the usual lesion of syringomyelia, a cavity in the cord, more or less triangular in shape, in this case, and extending from the sixth cervical to the sixth dorsal roots. The part involved was almost entirely the left posterior horn, the anterior horn being left almost completely intact. The interesting aspect of the pathologic anatomy for Marinesco lies in the fact that lesions of the left posterior horn should give the trophic troubles incident to Morvan's disease, localized entirely in the left hand. The inference is that the the medullary lesions of Morvan's disease have their seat in the posterior horns, and that it is here, as a consequence, that the trophic centers for the integumental and skeletal tissues of the extremities are to be found. A careful bacteriologic investigation did not disclose the presence of bacilli. The cavity in the cord was, as is usual in syringomelia, the result of a gliomatosis of the periendyma, the process seemingly starting in the canal, and spreading to the posterior horns. Jeanselme reported that he had not been able to find bacilli in the anesthetic spots, either over or under pigmented, as they accur in Bretagne, the home of the disease. As Hansen's bacillus is not often found in the trophic lesions of leprosy, however, Jeanselme did not consider that he could base any satisfactory conclusion on his negative results.

THE
Journal of the American Medical Association
PUBLISHED-WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
Per Annum, in Advance $5.00
Foreign Postage 1.75
Single Copies . . . . 10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 21, 1897.

POLITICS AND THE MEDICAL PROFESSION.

Whatever may be one's private opinions as to public questions, to whichever party he may have belonged in the past, it is clear to all independent intellects that there are other duties to one's fellow-men and to the future far more imperative and binding than allegiance to any political party—so far at least as such parties are at present constituted and used. Both great parties in American politics have at times fallen away from their principles and have wallowed in such bogs of corruption that they have nauseated their best members into a condition of alienation and independence, or at least into one of irritation and half contempt. One votes as he does now-a-days not because he likes Cæsar less, but that he likes Rome more; not because he believes much in the men, their acts or principles, on the ticket, but because he believes rather less in the men and their doings whose names are on the other tickets. It is too frequently a choice between two evils, in which one has some difficulty to determine which promises or rather which will fulfil the least evil. All of this is not, perhaps, wholly to be deplored; it has many advantages, not the least of which possibly are a more intelligent conception of and participation in government affairs; a use of parties and partizanship as mere instruments and tools for purposes beyond their surmise; and a habit of independence which may come in time to control the corruptionists. When these schemers and bribers and hoodlums, "in it for what it is worth," are dictating legislation and controlling law for their unscrupulous selfishness, men who have better purposes in life may be not only excused but encouraged to put in such delegates and lawmakers as will protest against abuses and use their offices for the public good.

Beyond all question things have come to such a pass that for medical men matters pertaining to professional and sanitary welfare must henceforth outweigh all considerations of partizanship. Questions of tariff, whether for revenue or for protection, questions of currency, etc., are infinitely unimportant in comparison with questions of professional progress and the health of the people. It is a shame for medical men to sell themselves in future for the advantage of politicians and commercial interests, while the far higher and more vitally important questions of scientific advance and the cure of disease are utterly neglected. It is our inescapable duty henceforth to judge of men and parties from the professional standpoint, and to make our power felt with administrators and legislators for purposes other than those represented by lobbies and bosses.

There are several methods whereby medical men can influence their administrative and legislative servants: 1. The first and most important is by corporate action, resolutions, committees, etc., through medical societies. Strange as it may seem, this, by some physicians, is considered unprofessional and *ultra vires*. The very thing we should do, that precise method of making our influence felt which is most effective and most imperatively demanded is, wonderful to say, actually the thing at which we balk and stop. No matter what disgrace to medicine may be threatened, no matter how clear the professional duty that confronts us, there are today not a few of the so-called leaders—professional tories and aristocrats, they might be termed—who say, "Oh, yes! It is all a miserable shame, but *non possumus*! Our organization gives us no right or power to go into politics." Bah! This is the voice of laziness and cowardice; it is not the way of scientific advance or of the cure and prevention of disease. Medical societies have not only the right and power, they have the inobviable duty laid upon them, shirk it and deny it as they may, to make their influence felt in all public questions relating to the public health. The work of the British Medical Association and of its parliamentary and other committees in eradicating abuses and in instituting reforms, gives the lie to our pusillanimity and, by example, illustrates what may be done by men whose motives are pure and whose bravery puts their motives into action. Every American medical society from the smallest to the largest is under the most stringent obligation to make matters of the public health its most direct concern. Each one, and especially the AMERICAN MEDICAL ASSOCIATION and the Medical C [illegible], shoul [illegible] ss reso[illegible] tions pertaining to bad [illegible] se [illegible] od l that should be proposed, in reference to medical education, quarantine, health-protective measures, etc., and should see that copies of these resolutions are placed in the hands of every legislator and administrator to whom they concern. Only thus shall we make our professional will and power known, and in becoming known it shall bring about reform and social education. Our organizations should also appoint committees, and see that these committees do their work to bring to the consciences and consciousnesses of the public officials their duties as to the prevention and cure of disease.

2. Not only by means of our organizations can we further our cause, but hardly less effective, if strenuously carried out, would be the work of individuals of the profession should they try to influence their lawmakers and administrators in a private way. If these men are known to us personally, by all means protest and advise by word of mouth. Incalculable good could be done so. If the powers that be are not our acquaintances or patients, there remains the letter-carrier to help us. And a powerful influence is the written letter! When a vicious piece of legislation is proposed, or when good measures are neglected, we should write to legislators and governors and mayors in condemnation or in commendation. Many a shameless bit of medical jobbery is smuggled into law simply because the men with power hear only the quacks' side and not a word is uttered by us who are the appointed guardians of the nation's health. The few quacks combine, hire a lobby, write a thousand letters, appoint committees, personally intercede and win the day, while we, who are 100,000, meet in a thousand societies, local, State and National, and talk about headaches, sprains and sore toes, but never a word about prevention or cure of the common professional and social miseries that afflict and murder millions. The profession by such silence is not only renegade to its humanitarian function, but it is renegade to its own self-interest. A man may not always be his brother's keeper, but a physician is always so, and when he denies or neglects the fact he is a shirker and at heart and in fact an enemy of his own guild.

While we acquiesce in silence, physicians who value their selfish aims and interests above those of the world and of their profession, form a compact and make a raid on the public treasuries for endowments and "divvies" for the benefit of hospitals, dispensaries and medical colleges founded and carried on not for the public good but for the benefit and profit of the lobbyists. All the time there is not one in a thousand of the epileptics of the land cared for, his life turned from a curse to a blessing by the one sure method which we all know. Is this medicine? Is it humanity? A hundred such examples of abuse and disgracefulness arise spontaneously in every reader's mind, and need no further listing. The antivivisectionists, the meat-sellers and milk-dealers who are only kept from sewing the seeds of disease by inspectors and legal control, go on with their infamous traffic because, forsooth, we do not care or because the stoppage of the misery is *ultra vires!* Can a more flagrant example of professional cowardice and stultification be cited? Shall it go on forever, while eternally postponing we sing the old woman's song:

"Consider, good cow, consider!"

THE COMPARATIVE PATHOLOGY OF MALARIA.

Of late years there have been described by various investigators certain forms of parasitic blood diseases in animals that undoubtedly correspond to the now quite well understood malarial diseases of man.

BABES[1] of Roumania, was one of the first to investigate the occurrence of parasites in the red blood corpuscles of cattle. It concerned an acute febrile disease, occurring in the summer, lasting from four to seven days, and characterized by a hemoglobinuria that made its appearance on the second or third day and which was constant in the fatal cases. Postmortem there was found hemorrhage in the kidneys and in the walls of the stomach and intestines, and acute splenic swelling. The red blood corpuscles contained one or more parasites shaped like cocci, but BABES could not follow the stages of development of the parasites, whose exact nature was not established.

The most important investigations concerning this disease have been made by THEOBALD SMITH[2] now of Harvard University, whose studies of Texas fever have called forth universal admiration on account of clearness, accuracy and penetration. In the acute form, which usually occurs in the summer, there is fever, anemia and hemoglobinuria, the disease being generally fatal. The postmortem shows acute splenic swelling and hemorrhage into the substance of the kidneys. The red blood cells show, in the fresh preparations, ameboid protoplasmic masses, often paired and bean-shaped; in the fixed and stained preparations red corpuscles laden with chromatin fragments are also found due to the destruction of embryonal cells. The chronic form occurs in the autumn and may pass unnoticed, hemoglobinuria being rare; the parasites are usually round, small-like cocci. The disease can be produced experimentally by inoculation of the blood of one animal into another. SMITH calls the parasites *pyrosoma bigeminum* and regards them as related to those in the red corpuscles in malaria, human and animal; in all probability certain suctorial parasites (*ixodes bovis*) play an essential role in spreading the disease.

[1] Sur l'hemoglobinuria bacterienne du bœuf. Acad. des Sciences, 1888 and 1890. Die Aetiologie der seuchenhaften Hemoglobinurie des Rindes, Virchow's Archiv. Vol. cxv, 1889.

[2] Preliminary observations on the microorganism of Texas fever, Med. News, 1889 Also eighth and ninth annual reports of the Bureau of Animal Industry, 1893.

Ali Krozius and v. Hellens[3] described endemic hematuria of cattle in the swampy regions of Finland. These authors regarded the parasites they observed as most likely identical with those already described by Babes and Smith.

Sanfelice and Loi[4] examined the hematuria of cattle in Sardinia, where it is wide-spread, and concluded that the disease is identical with Texas fever, and the hemoglobinuria of Roumania and Finland.

Very recently Celli and Santori[5] have published the results of their studies of a similar or identical disease occurring in that home of malaria, the Roman Campagna. Their paper is accompanied by a plate illustrating the blood findings. The disease is characterized by fever, acute anemia and endoglobular parasites that probably occur in two forms, but the complete developmental cycles of the parasites have not been traced. In some of the severe cases of the disease hemoglobinuria appears, but this is not so constant or frequent that hemoglobinuria or hematinuria of cattle can be considered as suitable names for the disease. Quinin exercises a curative action in this infection, and for this and other reasons the disease is designated by these authors as *rinder-malaria* or malaria of cattle, a term that seems to the writer at once appropriate, accurate and significant.

Celli and Santori regard this parasitic affection as in the main identical with the hemoglobinuria of cattle in Roumania (Babes), Texas fever (Smith), the hemoglobinuria in Finland (Krozius and v. Hellens), and the hematinuria in Sardinia (Sanfelice and Loi). The wide-spread occurrence of malarial diseases of cattle may therefore be regarded as established on account of the clinical manifestations, the form and endoglobular situation of the parasites, the nature of the anatomic changes, the development of the disease in malarial regions and in malarial seasons and the curative action of quinin.

This malaria of cattle, though it resembles in the main that of man, presents certain differences. It seems that while the parasites destroy the blood corpuscles and thus cause anemia and not infrequently hemoglobinuria, yet they do not form black pigment and hence melanemia does not occur; in this respect the disease resembles more the estivo-autumnal and rapidly malignant human malaria. Bovine malaria is transferable from animal to animal belonging to the same race or species. The anatomic changes are quite analogous to those of certain forms of human malaria; the changes in the kidneys, the spleen and the liver are stated by Celli and Santori to be quite similar to those found in malarial hemoglobinuria in man by Bastianelli.[6] The geographic and seasonal occurrence of bovine malaria corresponds, as indicated in the foregoing, very strikingly with that of the human form. And finally the favorable action of quinin completes the analogy of the two kinds of malaria (Celli and Santori).

In connection with this it is interesting to note that the comparative parasitology of the red corpuscles recognizes not only a human and, as set forth, a bovine malaria, but also endoglobular or malarial infections in frogs, reptiles and birds. Quite recently the investigators in the Johns Hopkins Hospital of Baltimore[7] have demonstrated the occurrence of malaria in certain indigenous birds, showing that the endoglobular parasitic avian diseases are also wide-spread distributions. Observations are also at hand that indicate that sheep, horses and dogs may be subject to similar invasions.

TRAUMATIC ENDOCARDITIS.

It is pretty generally recognized that serious lesions of deep-seated organs may result from traumatism that is unattended with obvious external injury, and especially when the affected viscus is already the seat of disease. Thus the lung may be torn, the brain lacerated, a heart-valve rent asunder in consequence of violence expended upon the bony coverings of these parts, though perhaps without severance in continuity. Through the same mechanism may take place laceration of an eroded pulmonary vessel or rupture of a cerebral abscess or of a thoracic aneurysm. In all likelihood similar influences may give rise to inflammatory reaction, as manifested by pleuritis, or meningitis, but additional evidence is needed to convert probability into certainty.

In an interesting communication presented recently to the Berlin Society for Internal Medicine Litten (*Berliner klinische Wochenschrift*, June 28, 1897, p. 571) makes a valuable contribution to the subject of traumatic endocarditis. He points out that the injuries to which the heart-valves are susceptible consist in detachment, separation, contusion and laceration of the endocardium, with subserous hemorrhage. These may occur in the absence of all evidence of external injury, even in cases that progress to a fatal termination. Cases in which merely existing compensation for a preëxisting valvular lesion is deranged as a result of traumatism are of course not instances of traumatic endocarditis and do not belong in the category of those under consideration. Those cases also are to be excluded in which as a result of traumatism at any portion of the body microörganisms gain entrance to the circulation and localize themselves upon the endocardium. These represent instances of septic endocarditis secondary to general infection. Most of the cases heretofore described [illegible] traumatic endocarditis have been [illegible] those cases are considered in this connection in which simple benign verrucose endocarditis develops in direct relation with a previous injury to the chest. In the accurate determination of this relation it is essential that the state of the heart before or at the time of the reception of the injury shall have been known, as well as that at varying periods afterward. Litten relates three in cases which he believes such a relation to have been established. One occurred in a young man, previously healthy, who was crushed between his horse and a resisting surface. The resulting pain was so severe as to cause the man to fall. When examined he complained of a feeling of anxiety, palpitation of the heart, a sense of oppression and dyspnea, with fever and cyanosis. After the lapse of several months a loud systolic murmur was heard at the apex of the heart and one also over the aorta, together with enlargement of the right ventricle and in less degree also of the left. A diagnosis of mitral insufficiency and aortic endocarditis leading to aortic obstruction was made. While in this case the endocarditis was followed by a valvular defect, in the second case reported perfect recovery ensued.

[7] Johns Hopkins Hospital Bulletin

A laborer employed in the construction of a bridge received a heavy blow in the left side of the chest which rendered him, unconscious. He suffered from dyspnea, palpitation of the heart and pains in the chest radiating toward the shoulder, with cyanosis and a small, frequent pulse. The heart appeared to be normal, and recovery had taken place after the lapse of four days. The heart sounds were pure, though feeble. On the fifteenth day a systolic murmur was audible at the apex and gradually increased in intensity. No hypertrophy of the right ventricle could be made out. After the lapse of nine months the murmur had entirely disappeared and could not be induced by active muscular exertion.

The third case occurred in a man who had long been under observation on account of an esophageal diverticulum and had never presented any cardiac abnormality. While ascending a ladder with some stone he fell backward and received a heavy weight upon the left side of the chest. When shock had been recovered from, the heart sounds were found normal for several days. After the lapse of a number of weeks a systolic murmur could be heard, indicative of mitral insufficiency, with hypertrophy of both ventricles.

Numerous cases like the foregoing have been reported, but they lose much of their significance because the condition of the heart immediately after the accident is not noted. Many months may elapse before a murmur becomes audible. A distinction must be made between the traumatic rupture of healthy and that of diseased valves. The latter may take place spontaneously; it is the more common and usually affects the aortic valve. Under these circumstances manifestations of aortic insufficiency set in suddenly and the condition is readily recognized. Laceration of the mitral valve has thus far not yet been observed but only that of the chordæ tendineæ and of the papillary muscles. The prognosis of traumatic aortic insufficiency is more unfavorable than that of the spontaneous variety. Death often occurs before hypertrophy of the left ventricle can take place.

CAISSON DISEASE.

The extraordinary strides which have been made in science and in the arts during the last fifty years have developed ailments which practitioners of medicine previous to the last half century were entirely unfamiliar with, and one of the most interesting of these, from an etiologic and pathologic standpoint, is that condition which has, because of its causative factor, been named the "caisson disease." The great number of large engineering ventures has increased the opportunity for the study of this interesting condition, and in this country the most noteworthy studies which have been made concerning it have been those of Jaminet, who studied the condition of the workmen who were affected by this ailment during the building of the St. Louis bridge, and A. H. Smith of New York, who has carefully recorded the observations which he made upon a similar class of patients during the excavations which were made for the foundation of the Brooklyn Bridge. Still more recently a most careful and accurate study has been made by Dr. Hugh Snell during the excavations required for the foundation of the piers of the celebrated Forth Bridge in Scotland. This observer has published the results of his investigations in a little monograph which has recently been published by H.K. Lewis of London, and in it he discusses the history of the disease, the studies which have been made in regard to its physiology and pathology, and the researches of Triger, Paul Bert, Francois and others. After doing so he draws upon a rich store of over 200 cases which he has carefully observed for his own remarks.

It is useful in this connection to notice some of the other work which has been done in regard to the study of this affection, which from the time of its earliest recognition has proved itself a never-ending source of interest. It will be remembered that the symptoms of the malady usually develop only when the patient returns to the ordinary atmospheric air, emerging from a caisson in which the atmospheric pressure may have been several times that of the normal atmosphere. The mildest symptoms are dizziness and vertigo with some neuralgic pains in the head, but if the pressure has been high, or the individual is susceptible, these neuralgic pains become most excruciating, darting with fearful velocity about the arms and legs and the head and trunk, and becoming so intense that the patient often declares that the flesh is being stripped off his bones. At the same time there is complete abeyance of the tactile and pressure sensibility. Nausea and vomiting may come on preceded by violent paroxysms of epigastric pain and sometimes, although more rarely, there is relaxation of the sphincters. In some instances the pain is absent and the paralysis is the dominant symptom. If coma follows the vertigo or paralysis, death is invariably the result, although in the absence of this symptom the prognosis is fairly favorable. It is a matter of interest to note that the pain is the most constant and well-defined symptom from which the patients suffer.

The theories which have been advanced to explain this extraordinary series of symptoms have been numerous and antagonistic. Snell believes that they depend upon the pressure itself, the length of stay in the compressed air, improper ventilation, too rapid return to the normal atmospheric pressure and lastly to personal idiosyncrasies. From a careful study which we have made of this subject we believe that the symptoms are frequent in direct ratio to the degree of pressure to which the patient has been subjected, for statistics certainly prove that whenever the pressure is two or three times that of the atmospheric air these symptoms develop in a large number of workmen; whereas if the pressure has been only slightly raised above that of the ordinary atmosphere "caisson disease" seldom asserts itself. That a greater pressure than that of atmospheric air is a direct etiologic factor in producing the primary condition which ultimately results in the development of these symptoms seems to be proved by the fact that careful clinical studies by Junod, Sandahl. Pravaz and von Vivenot show that there is great peripheral displacement of blood in patients exposed to high pressures in a caisson, with the result of producing great congestion of the internal viscera. To such an extent may the peripheral circulation be cut off by high atmospheric pressure that even the radial pulse may be lost, as in the experiments made by Waldenburg. The resistance which is offered to the peripheral circulation often slows the heart from 30 to 36 beats per minute, although such a degree of slowing is not common.

The question therefore arises, do the symptoms of caisson disease depend upon this altered circulation with the sudden return of blood to the peripheral capillaries upon the return of the patient to ordinary atmospheric pressures, or is there a more deeply underlying cause for these symptoms? A certain number of investigators have believed that there is an underlying cause which consists in the fact that under the high pressure named the blood absorbs an excessive quantity of the gases of the atmospheric air, of oxygen or nitrogen, and that the sudden setting free of these gases produces the hemorrhages and other lesions of the nervous system which are found in those cases in which death occurs. Liebig and Bert have proved positively that the absorption of oxygen in compressed air is increased. Paul Bert also claims that the quantity of nitrogen in the blood is materially increased, and he asserts that he has found bubbles of this gas in the blood vessels when the pressure was as high as five or six atmospheres.

It seems to be pretty well proven, however, that the symptoms can not and do not depend upon the excessive absorption of either oxygen or nitrogen, and we therefore turn with interest to the theory advanced by Jaminet of St. Louis, that the symptoms are due to the overloading of the system with effete matter which is set free throughout the entire circulation by the return of the patient to the ordinary atmospheric air. Careful studies which have been made of the ordinary and respiratory exhalations made in the caisson seem, however, to contradict this theory. We accordingly return with interest to the statistics which have been collected by Snell, in the work already quoted, which seem to prove that inadequate ventilation exercises a very material influence in developing the symptoms which we are considering. Snell has made a series of convincing experiments which seem to prove his assertions. Thus when the men were working in a pressure up to 20 pounds above the normal atmosphere with a supply of fresh air of less than 4,000 cubic feet per man per hour 16 cases of illness occurred. When from 4,000 to 8,000 cubic feet per man per hour were supplied only 9 cases occurred, and when above 12,000 cubic feet per man per hour no cases occurred.

It seems evident, therefore, that very high pressure and poor ventilation are two causes which certainly exist, and we can pass on to a study of two other causes which are apparently equally potent factors, namely, the too rapid passage of the patient from a high pressure to that of the ordinary atmosphere and the presence of personal idiosyncrasies. In the first place it is reasonable to suppose that the patient passing from a high atmospheric pressure to a low one with great rapidity, immediately after passing through a number of hours of exhausting toil, might develop symptoms similar to those which have received the name of the "caisson disease," and in the second place it has been proved that if the workmen pass slowly from a high pressure to a low one they as a rule escape the manifestations of the malady. For this reason a number of engineers have provided caissons containing air at different pressures, and have forced their workmen to spend from half an hour to an hour in passing from the lowest caisson to the surface of the earth, thereby saving a number of lives and preventing much illness.

In regard to personal idiosyncrasy it is interesting to note that certain types of men are much more prone to the disease than others, and this fact seems to us to militate strongly against the view promulgated by

Bert, the more so as the workmen usually become habituated to the exposure so that veterans are far less liable to the disease than novices. If the symptoms were due entirely to physical causes such as the absorption of increased quantities of oxygen and nitrogen it is fair to imagine that immunity could be speedily obtained. It certainly is a fact that in those persons who have a large peripheral circulation caisson disease manifests itself more frequently than in those who have a more limited area of peripheral capillaries. Thus in Smith's observations at the Brooklyn Bridge out of thirty-nine men with a tendency to corpulency only three escaped illness, while out of fifty-three lean and lanky men twenty-five escaped. Of the thirty-nine stout men eight were more or less paralized, while of the fifty-three slender men only two were paralyzed, and the deaths which were three in number were entirely among stout men.

It is interesting to note that Snell also believes that rapid decompression is a causative factor in the majority of cases and also thinks that it is the increased solution by the blood of the gases contained in the compressed air, and the liberation of these gases on the pressure being removed, which is chiefly responsible for the pressure symptoms he has described. Whether he be correct in this view or not we at least have obtained the therapeutic point that slow decompression is a *sine qua non* in the prevention of this ailment, as is also good ventilation and also that in superintending the engaging of men for this form of labor only those should be engaged who lack corpulency, and who therefore have not a predisposition to the disease.

THE APPARENT INCREASE OF SUICIDE.

The *Spectator*, a life insurance publication, gives the mortality from suicide in 1895 and 1896 in thirty of the chief cities of this country containing nearly ten million inhabitants or a little over 50 per cent. of the total urban population of the country. The statistics are reliable, having been carefully compiled, and they show that the number of suicides increased from 1,826 in 1895 to 1,999 in 1896, or 9.5 per cent. The estimated average annual increase of population in these cities is only 4.6 per cent., or less than half the increase in the suicides. Of the thirty cities, only nine showed a decrease or a stationary figure, which, allowing for the normal increase of population, is the same thing as a decrease; and it is noteworthy that among these were several of the largest centers of population, as Chicago, Brooklyn, Cincinnati and St. Paul. In New York the increase was very slight and the same might be said of some other large towns. The largest proportional increase seems to have been in some of the smaller cities, as Portland; but this indicates little, as any increase would be proportionally large if the original figure were small.

The apparent important fact in the above figures is the proportionate increase as compared with that of the population, which is in its way significant. An increase is by itself not specially noteworthy, as that is the rule in civilized countries, as was demonstrated twenty years ago by Lombroso in his monograph on this subject. A jump, however, in one year of over 9 per cent. while population only increased at half that rate indicates a more active set of causes for this crime of self-destruction. Hard times is the most obvious of these, but this can not alone be credited with the phenomenon; the political and other excitements of the past year have undoubtedly been, to some extent, efficient in bringing about the result. The country is not necessarily getting insane, suicide is not in itself an evidence of mental derangement, but it does seem, judging from events that are occurring daily, that there has been and still is an abnormally hysteric tendency existing at the present time in our population, and to this we may perhaps credit a part of the unusual increase of suicides. While hard times do not appear to increase the aggregate consumption of alcoholic liquors, one can not say that the well known effect of these in the causation of suicides is materially diminished; the decrease of alcoholic consumption is among those who are not seriously the victims of intemperance, the class that furnish the suicides from drink.

Reckoning the aggregate population of these cities in round numbers as ten millions, we have a lower figure per million than existed even twenty years ago in most European urban populations, and this is, so far as it goes, an encouraging fact. Even if it is assumed that many cases are unrecognised or otherwise escape registration, the figures are still comparatively favorable, for the same possibilities exist elsewhere. Brierre de Boismont, for example, estimated that fully half the cases in Paris were unrepresented in the statistics, and Strahan more recently has expressed the opinion that, for most civilized countries, this estimate is well under rather than over the truth. Statistics are, however, constantly becoming more accurate and complete, and it is probable that these figures are less open to the charge of imperfection than most of those considered by Strahan. The fact, therefore, that they show an increase is only to be expected, and this may possibly only correspond with a proportionate decrease in the unrecognized cases. The further fact that they show an actual decrease in some of the largest cities is encouraging, especially when account is taken of the special conditions that have existed, as already noted, and which might naturally be expected to favor an increase of suicides. The ineffectiveness of any legal prohibition is indicated by the slight increase in New York, where attempts at suicide are a penal statutory offense. The successful carrying out of a crime in this case, unless it be considered its own penalty, which is evidently not the view taken by the offender, practically bars out its punishment and possibly something in the nature of the old-fashioned postmortem penalties might be more effective.

The causes and motives of suicide are so various that any generalizations that may be made are open to criticisms, but one thing is probably fairly established, viz., that its increase is favored and promoted by the stress and competition in modern civilized life. It is one way and that not the least obvious one, in which the degenerates and weaklings eradicate themselves from our populations; to a certain extent it is feature of our social evolution. The statistics such as we have given above are not on the whole discouraging; they do not point to such a state of affairs as exists in many countries as regards this particular indication of national degeneracy. Considering the mixed character of our population, the tendencies to discontent existing and encouraged at the present time, the spread of irreligious and pessimistic doctrines among the uneducated or partially educated masses, all facts that favor suicidal increase, it can not be said that the data, so far as known, show even as great a frequency of self-murder as might be looked for. Apart from those cases due to the natural increase of insanity, the figures seem almost encouraging, if such a thing is possible in statistics of this kind.

BRITISH MEDICAL ASSOCIATION—SPECIAL RATES.

The Grand Trunk Railway System will sell reduced rate tickets to all physicians attending the British Medical Association meeting at Montreal, August 31 to September 5. Tickets will be sold August 28, 29 and 30. good returning three days after adjournment of the convention, at rate of one and a third fare for the round trip. Through Pullman palace vestibuled sleepers daily between Chicago and Montreal. For tickets and sleeping car accommodations apply to L. R. MORROW, G. P. & T. A., 103 Clark St., Chicago.

CORRESPONDENCE.

The Treatment of Typhoid Fever—Final Reply of Dr. Woodbridge.

CLEVELAND, OHIO, Aug. 14, 1897.

To the Editor:—Will you accord me a little space to reply to Dr. Upshur's most remarkable communication in the current issue of the JOURNAL? (*Vide* JOURNAL, August 7, p. 293.) "It is true, I do not possess a knowledge, either 'theoretic or practical,' in line of the Woodbridge methods."

The above excerpt from Dr. Upshur's letter coupled with the author's admission that he took the quotations for his recent paper from an advertising circular will enable physicians to form a just estimate of the value of his criticism of the "Woodbridge Treatment of Typhoid Fever," and suggests a new title for the paper. In view of the antiquated methods which he advocated, how would this do: "Scraps of Ancient Medical History, with a Criticism of the Scientific Treatment of Typhoid Fever, that is based on total ignorance of the subject, supplemented by free and elaborate quotations from an advertising circular."

Dr. Upshur, apparently to emphasize his ignorance, even of the best methods of disinfection, asks questions about the use of formaldehyde gas, with which he ought to be perfectly familiar, since a knowledge of it has been freely circulated through the medium by which *he* seems to obtain his knowledge of medicine, *i. e.*, advertising circulars. The space in the JOURNAL that would be required for full explanations is too valuable to waste in communicating knowledge which may be easily obtained from books or "advertising circulars" and with which every physician in the United States, except Dr. Upshur, is probably already familiar, but for his benefit I reproduce the following quotation from Dr. Kinyoun's report of the disinfection of a room of the "capacity of 7,400 cubic feet; percentage of formaldehyde, 0.5; time, 23 hours . . . d. cultures spread on cover-slips, placed in double envelopes, the inner one sealed with paraffin, and enveloped in thirty-six layers of new cotton sheeting; anthrax, no growth; diphtheria, no growth; typhoid, no growth; s. pyogenes aureus, no growth."

If Dr. Upshur had attended the meeting of the American Public Health Association last year, or if he would read its journal, he would not have to "leave it to a discriminating profession" to decide whether a room will be better disinfected by the use of formaldehyde gas or by his troublesome and obsolete methods, or if he will turn to page 96 of volume 12, number 5, Public Health Reports, he will find the answer to his question, "What does he send it in with?" in these words (following the description of the apparatus used) "a small one eighth inch pipe is attached and passed through the key-hole of the door of the apartment." If the Doctor will procure some advertising circulars and read up carefully the subject of formaldehyde gas he will find his witticism "it seems to me a consistent suggestion and as gassy as his other assertions" turned against himself, since there is abundant evidence of the superiority of formaldehyde gas over all other disinfectants, if the distinguished gentlemen who have investigated the matter so thoroughly have made no mistakes.

The Doctor thinks it "strange" that I have not criticised his quotations from Tyson and Wilson. There are two reasons: 1. I have not their books and hence I have no reliable information that *they* have noticed me or my work, and also I have no assurance that the quotations are correct or were not taken from an advertising circular or a medical almanac. 2. I am replying to Dr. Upshur not Drs. Tyson and Wilson. I am criticising Dr. Upshur, not because he criticised me or the method I advise, but because, in a state of confessed ignorance he assumed the role of teacher, and within a few hours of his admission to membership in the AMERICAN MEDICAL ASSOCIATION he stood up in one of the Sections of that learned body, made statements that are not sustained by facts, violated the spirit and letter of its code of ethics, made an unprofessional assault on a large number of its most progressive members, transgressed the unwritten law (which makes the word of a medical man on medical questions supreme) by saying, "the testimonials" (the clinical and other reports of physicians) "are not worth any more than the testimonials given by hundreds" (by quacks or their patients) "to the so-called cancer cures and kidney cures *et id omne genus*," and when his attention was called to the seriousness and extent of his offense, he attempts to justify his transgression by slandering the medical profession again in the following words: "There are hundreds of good men who fail to analyze cases and treatment." Does Dr. Upshur wish it to be understood that there are "hundreds of good men" who assume the responsibility of guarding the lives of their patients through such a disease as typhoid fever, and who do not make sufficiently careful analyses to know what they are treating and how? Does Dr. Upshur know of any grosser outrage against the dignity and honor of medicine or any greater perversion of truth than to declare that the reports on any method of treatment made by educated physicians who have given the subject careful study at the bedside of large numbers of patients, are comparable to those "testimonials" that accompany "quack nostrums," or does he insinuate that there would be any difficulty in drawing the distinction between them.

The Doctor says: "If he is *disingenuous* enough to take my quotations in my article and compare them, he will find the quotations accurate to the letter," etc. My answer is that while I may be "*disingenuous*" enough to make the comparison, I have not the advertising circular to which he alludes; so here we have his admission that he reviewed a great medical question, on the solution of which hundreds of thousands of lives may depend, from an advertising circular, and when he is driven to the wall he confesses that he has neither "theoretic nor practical" knowledge of the method which he condemns. Such recklessness of human life would do honor to the spirit of the Borgias!

Dr. Upshur boasts that he is in "very good company" and names gentlemen who would probably not subscribe to his ideas of treatment, who would certainly contradict his assumption that his method of disinfection is better than the use of formaldehyde, who would unquestionably repudiate his derogation of the dignity and honor of physicians and medicine, and yet it is probably true that at the present time they would agree with him in rejecting the abortive treatment of typhoid fever. I am sorry, for I would gladly have these princes in medicine with me and with the host of progressive men who know that the disease *can be aborted* and are brave and true enough to say so. How quickly victory would perch upon our banners. But when human lives are at stake, I would rather be right and be alone, than be wrong and be the intimate of kings and emperors. JOHN ELIOT WOODBRIDGE, M.D.

A Circular Letter to Leprologists.

NEW YORK, Aug. 13, 1897.

The following resolutions will be presented at the Berlin Lepra-Conference, Oct. 11 to 16, 1897.

Resolved, That it is the opinion of the delegates of Government, and the leprologists here assembled, that all goverments shall be invited to appoint official delegates (one from each country) to form a *permanent* committee for the suppression and prevention of leprosy, to meet first in Berlin in October, 1898; these delegates to be salaried by their respective governments, and to have full charge of all matters pertaining to leprosy in their own countries.

Resolved, That the German Government be requested to send this invitation through its state department to all governments concerned.

May I count on your support for having these resolutions passed? ALBERT S. ASHMEAD.

NON BIS, SED CENTIES, IN IDEM.

Independently of any differences between Dr. Ehlers and myself, which can only be side issues; independently of any priority question between Dr. Goldschmidt and Dr. Ehlers, as to the proposed measures against the progress and continuance of leprosy, I stand and have always stood for the formation of a *permanent* international committee for the suppression of leprosy. This is *my* idea, and my perseverance in presenting it, advocating it, defending it, fighting for it is the only originality I claim. Whoever has opposed it, whoever will oppose it before the conference at Berlin, during that conference or after it, will always find me ready to open this discussion again. The solution of the leper problem, which is a more tremendous problem than any privat docent sent to Iceland, where he looked at *102* lepers (not 159, as I thought before), can possibly *understand*, can only be reached by systematic, enforced, legal isolation. It is really no use writing books on etiologic studies in Iceland, for instance. These may bring recompense to the publisher, and glory to the author (who thus becomes one of the *renowned* leprologists, whose works are *known*), but what good does it do to the lepers? What to those who are exposed to the contagion? However "general" a secretary may be, of whatever lepra conference he may be the ruler and shining light, however grave and portentous a noise the conferential confabulation may produce, there still remains only one thing that can do any good, it is the thing which I have always proclaimed, and shall proclaim as long as I live.

I am in this question, situated like the old Cato, who never tired of saying: *Carthago delenda est.*

ALBERT S. ASHMEAD, M.D.

An Ancient Manuscript.

PHILADELPHIA, Aug. 9, 1897.

To the Editor:—I take it that nearly all physicians, and surely all the members of the AMERICAN MEDICAL ASSOCIATION, are interested in matters pertaining to our profession, be their source ever so indirect or remote.

It has seemed to me quite worth while to bring to the notice of the readers of the JOURNAL who are not already acquainted with the extraordinary find of Messrs. Grenfell and Hunt in Egypt last January, this item through your kindness. The discovery is that of a piece of papyrus containing in the Greek text eight unrecorded sayings or *logia* of Christ. The fifth saying has two gaps, rendering it incomplete; the eighth saying is not decipherable. Each saying begins with the words Λέγει Ιησοῦς—Jesus saith. Historic and archeologic critics and authorities seem to agree in believing that the *logia* are genuine, and the work of a transcriber of the second century (150 to 200 A. D.).

To physicians, interest will be directed especially to the latter half of the sixth saying, which reads: "No prophet is accepted in his own country" (similar to Luke iv: 24); "*neither doth a physician work cures upon them that know him.*" This reference to the therapists of Christ's time may perhaps be interpreted as a keen and penetrating observation of oriental medical results in ancient Judea, Samaria and the surrounding provinces. But, shall we be justified in restricting its applicability to the days and people of antiquity? Rather, does not candor and experience compel us often to acknowledge, with silent and sensitive disappointment in failure, the truth and force of this probable saying of Christ in modern practice?

Perhaps a train of wholesome thought may arise from a consideration of this long hidden testimony concerning the physician. Respectfully, H. S. ANDERS, M.D.

Resolutions of the New York County Medical Association.

NEW YORK, Aug. 13, 1897.

To the Editor:—The comprehensive and emphatic letter signed "Justitia," published on page 89 of the JOURNAL, July 10, comments upon a peculiar and unusual condition of affairs medical in New York city, and while Justitia would appear to be impartial, I am certain he wishes to be correct as well. I therefore quote part of line eight of the first resolution, viz., "was *vicious* in principle," etc., which should read "was *wrong in principle,*" etc., as recorded in the minutes of that meeting. Readers of the JOURNAL will appreciate the difference in the terms. M. C. O'BRIEN, M.D.

Recording Secretary New York County Medical Association.

PUBLIC HEALTH.

Co-operative Sanitorium.—An association has been recently organized at Vienna to erect a sanitorium for persons of moderate means, to which the physicians interested can send their patients and continue to treat them there personally. The charges for board at the institution will be no more than is required to cover the actual expenses.

Health of Denver, Colo.—The Bureau of Health reports eighty-nine cases of infectious and contagious diseases during July, with thirty-nine deaths therefrom. This is an increase of sixty two cases and twenty-five deaths, as compared to the month of June. Seventy-six were cases of typhoid fever with seven deaths. The total number of deaths was 166, an increase of forty as compared with June, 1897, and of twenty compared with July, 1896.

Protest against Our Quarantine Regulations.—At the meeting of the Cologne General Medical Association, June 29, Nockher spoke on "Hygiene on Shipboard," urging the necessity of hospital space with one bed to each twenty five persons, rigorous medical examination of intending emigrants, etc., concluding with a protest against the unrestricted powers allowed the quarantine doctors in North America and their often seemingly inappropriate and extreme quarantine regulations.—*Deutsche med. Woch.*, July 15.

Prophylaxis of Tuberculosis at Erfurt.—Our foreign exchanges are commending the new regulations at Erfurt, a town of 80,000 inhabitants, which not only requires the notification of every death from tuberculosis and free disinfection of the apartments, but also examines free of charge specimens of suspected sputa, on application to the bacteriologic laboratory, the first public institution of the kind free to the public for this purpose. If Koch bacilli are found the individual is carefully instructed in the necessary measures.

Fresh-air Fund for Paris.—Under the direction of M. Rambaud, of the Ministry of Public Instruction, a "children's fresh-air fund" has been started in Paris, on the same lines as that of the New York *Tribune* and similar to the one recently organized in London. The Paris fund is styled the "Maison de Campagne," and the children benefited thereby are those who attend the city schools. The mayors of the various districts of the metropolis form a part of the committee of management, and the scheme is conducted as in New York, by means of voluntary contributions.

The Water Supply of Boston, according to the *Sanitary Era*, is to be derived from a lake nine miles in length, covering 4,195 acres, 385 feet above high water mark and with an average depth of 46 feet. A busy manufacturing district in the valley of the upper Nashua River is to be obliterated, while mills, churches, schools, farms and the homes of 1,711 people are to wiped out in providing for this enormous reservoir. The State of Massachusetts, however, assesses itself for damages to property and losses of business and employment to the extent of from $30,000,000 to $50,000,000. The project is not yet out of discussion.

Convicts Gladly Producers.—A clipping from the *Brooklyn Eagle* informs us that work on the East Side lands was begun by fourteen convicts who were set to building sheds for the use of their fellows who are to undertake park-making. The problem of the Kings County Penitentiary is now likely to reach a satisfactory conclusion. "There are better ways," says the *New York Tribune*, "to relieve starving families than to keep convicts idle." Other accounts say that the prisoners, who were notably disturbed by the increase of suicidal forms of mania in their midst, were even hilarious over the probability of continuous work. It is well to state that "the chain and ball" on this occasion was not at all in evidence.

Anthrax Epidemic; Precautions May Avail.—A news item dated August 12, Clearfield, Pa., gives out that the Falls Creek tannery of Dubois, Pa., has closed down, owing to a foreboding anthrax epidemic. Four rather rapid deaths occurred among the employes who had bathed in a stream of water used by the tannery. Several cows suffered to roam at large also drank of the water and likewise died. Hides from China are suspected of being the cause of the unlooked for visitation, and the New York Board of Health having heard that "the Swamp," the great leather exchange of the city, had received some of the importation, made haste to trace out the lines of distribution. *Let us have a Department of Public Health!*

No Cigarettes for Indiana Minors.—A law has been passed in Indiana which makes it unlawful under heavy penalties for any corporation, company, firm or person to sell, barter, furnish or give, directly or indirectly, to any minor any cigarette, cigarette wrappers or any substitute for either, or to procure for, or to persuade, advise, counsel or compel any child under said age to smoke any cigarette. And it is made the special duty of prosecuting attorneys to enforce the provisions of this act, and they may summon any minor who may have or have had in his possession any cigarettes and compel him to testify before the mayor of a city or a justice of the peace as to where and of whom he obtained such cigarettes.

Costa Rica and the Yellow Fever.—Dr. T. M. Calnek of San José, member of the International Executive Commission of the Pan-American Medical Congress for Costa Rica, reports to the secretary, Dr. Charles A. L. Reed of Cincinnati, that practically all of the Pacific ports from Guayaquil to Acapulco are at this time infested with yellow fever. In consequence of the efficient inspection service maintained by the government but one notable case has occurred in Costa Rica. Marquis Gerolamo Martignone secretly visited the steamship *Don* of the English Royal Line which was lying at quarantine at Limon. He returned to the interior and developed the fever, from which he promptly died. Happily, the contagion was stamped out and no other cases have occurred. Costa Rica maintains an efficient service at Port Limon and other ports and has in contemplation the immediate establishment of a thoroughly equipped disinfecting station.

The Section of Hygiene at the Brussels Exposition.—The historic exhibits are interesting and the model dispensary, match and rubber factories, tannery, spinning room, etc., show the latest ideals in sanitation and hygiene. The exhibits of surgical and medical appliances are complete to date, among them an ingenious small case containing everything needed for bacteriologic examinations on the spot (Voituron and Screvens), with a display of specimens of microbian fauna. The exhibit of the magnificent results attained by the Superintendent of Schools at Limbourg with his Scholars' Temperance Societies, is much more impressive than the lurid pictures on the walls exhibited by the Anti-alcohol League, which, as the *Gaz. Méd. de Liège* remarks, only show the evils of drunkenness, but do not call attention to the greater evils that result from chronic intoxication from so-called moderate drinking.

Liable for Practicing Medicine.—Among the decisions handed down by the appellate court of Illinois, first district, is one affirming the judgment of the lower court for the plaintiff below in the case entitled Matthai v. Wooley. The latter party sued the former, a druggist, for ill consequences to him of alleged malpractice by the former as physician and surgeon. According to the evidence in behalf of the party suing, he thought the druggist was a doctor and went to him with a hurt finger, which the druggist wrongly treated for ten days, the result of which was inability to work for a long time and the final amputation of the finger. If the druggist did in fact "treat, operate on or prescribe for any physical ailment of" the plaintiff, the appellate court says the statute would regard him as "practicing medicine," within the meaning of Chapter 91, Revised Statutes of Illinois. And if by so doing held himself out to the plaintiff as a doctor and the plaintiff believed him to be a doctor, then, it says, he was chargable in that character. But the only question argued on appeal was as to the sufficiency of the evidence, which was very conflicting, to support a verdict for the plaintiff, and the decision was in his favor, as first stated.

Fire Closets.—A fire closet has been installed at the Nedlitz barracks near Potsdam which works admirably. The evacuations from the water closets are conveyed into a furnace below, where the solids are collected on a grating, while the fluids drain into a central receptacle. There are two fireboxes in the furnace, one opening directly into the chimney. This is always lighted first and not until it is burning clear is the other lighted. The latter consumes the fecal matters and evaporates the fluids, the draught from the first firebox carrying the fumes up the chimney and burning out all the gases. Coke or peat is used for fuel and about ten hours are required to incinerate the evacuations of 400 persons four days. For this 200 to 300 grams of fuel are needed per day and per capita, the expense of which is ten to twelve pfennigs. With this system incineration is not constant but only applied as needed.—*Journal d'Hygiène*, July 8.

The "Tiger Nut" Adulterant of Condensed Milk.—The convenience and cheapness of condensed milk, and its supposed better keeping properties, have led to its very wide use in spite of the serious drawbacks, arising from adulterated brands, to its adoption as a staple article of food for infants. The mysteries of composition of these inferior brands have not yet been satisfactorily revealed, but it is known that milk is by no means the only ingredient. The writer has it on good authority that at the present time a vegetable article is being largely imported, and being bought by certain milk manufacturers for the purpose of adulterating their wares. The adulterant is known commercially as the "tiger nut," and has the appearance of a rhizome, is no larger than the last joint of the little finger, and resembles a diminutive root artichoke. It is not unpleasant to taste, the flavor being strongly suggestive of condensed milk.—*Sanitary Record.*

Poisonous Ice Creams.—Evidence comes almost day by day, at any rate in the summer season, of the desirability of placing the manufacture of ice creams under definite control. There is no reason why an inspector should not be appointed to seize any materials intended for the preparation of ice cream that prove to be unfit for food, just in the same way as meat or any other article which is in an unwholesome state may be seized. As has been shown, the surroundings under which cheap ice creams are very commonly made are seldom cleanly, often loathsome in the extreme, and it is not surprising that recent bacteriologic inquiry has demonstrated the presence in them of the organism that is a normal inhabitant of the human bowel and it is well to bear in mind that any objectionable taste that the ingredients may have is not noticeable owing to the numbing effect of cold upon the tongue. Only recently an inquiry was held touching the death of a child, aged 14 years, who, four days after partaking of some ice cream obtained from a barrow in the street, died from ptomain poisoning. The postmortem examination showed that all the organs were healthy except the stomach, which was greatly congested, evidently by the action of an irritant poison. A verdict of accidental death was returned. There is little doubt that the ptomains were derived from bad eggs or perhaps highly decomposed milk. Seeing the great number of innocent juvenile partakers who are to be found round the barrows almost every day, it is high time that ice creams and the ingredients employed in their manufacture, should be subjected to the same control as are unsound meat, fruit, and tinned and other articles of food.—*Brit. Med. Jour.*

Sale of Adulterated Milk.—Rarely does a court brush aside technicalities and do more to carry out the spirit of the law than did the appellate term of the supreme court of New York, when it reversed the judgment given the defendant in the case of People v. Koch. This defendant was a wholesale milk dealer, buying and selling milk. He had no regular place of business, but took the milk which he bought from the railroad depot, in cans, in his wagon, and delivered it to his regular customers in the city. It was while he was thus delivering twenty-three cans of milk, early one morning, that he was stopped by an inspector, and a sample of milk was taken from one of his cans. This sample was analyzed by a competent chemist and found to be impure. Being sued for the penalty imposed by statute upon one who "offers or exposes for sale" impure milk, the defendant contended that he was not committing the offense charged, because he did not deliver to any customer the can from which the sample was taken, but returned it to the dealer at the depot from whom he bought it, and was credited with the price. If this contention should be considered well founded, then, said the court, whenever a dealer who has placed impure milk on sale is detected, and withdraws it before any of it is actually disposed of, he can not be convicted. But it does not think it could be contended that a milkman going his daily rounds to retail customers, to supply them with impure milk, would not be deemed to be offering and exposing milk for sale, and the defendant's case, it said, was no better. The justice should therefore have held that an offense was committed, and should have imposed the penalty fixed by law. The fact that the defendant subsequently returned this particular can to the party from whom he bought it, the court said, did not bear upon the question in dispute, because it was not shown that he intended to submit the milk in his wagon to an examination or test before delivery.

Progress Toward an Official Recognition of Bovine Vaccine by the British Government.—The London *Lancet* states: The answer given by Mr. T. W. Russell in the House of Commons, on behalf of the president of the Local Government Board, on the question of vaccine lymph, indicates the probability of a very important change of practice in England. Sir William Priestley had asked a question relating to the future government lymph service and he elicited two pieces of information. The first was that changes had already been made permitting public vaccinators to use calf lymph. This we had announced some time since and, as we explained, the permission means that no public vaccinator resorting to calf lymph will lose his award by reason of his failure to maintain a series of arm-to-arm vaccinations. The second statement related to inquiries that had been made, in foreign countries, by Dr. Thorne and Dr. Copeman, and to the probability that, in consequence of these inquiries, glycerinated calf lymph will come to be the future supply of the National Vaccine Establishment, and that this supply is likely to be a gratuitous one. If the supply turn out thus to be gratuitous a considerable change will be effected. Hitherto the proceedings of the Vaccine Establishment have been limited to the gratuitous supply of a small amount of lymph with a view of starting a series of vaccinations which were to be continued by a vaccination direct from arm to arm. But a gratuitous supply of glycerinated calf lymph in itself carries with it the abolition—in so far as the Government is concerned—of the use of humanized lymph; and hence the new supply can not be limited as formerly, but must be so contrived as to meet all demands of registered medical practitioners for all their vaccinations. This will mean a complete change of the existing system; and we can quite understand, as implied in the answer given in the House of Commons, that there may be difficulties in giving effect to the new system until the whole question of our vaccination law has been dealt with by new legislation. The existing law is based on the assumption that it is desirable to vaccinate with fresh humanized lymph from arm to arm; our future law will probably be based on the assumption that it will be best to vaccinate with stored glycerinated calf lymph. The two systems are scarcely reconcilable, and we can well understand that the latter system can hardly be brought into efficient working so long as it is controlled by legislation intended to secure a totally different result. However satisfactory the answer may therefore be, we shall probably have to wait until next session before effect can be given to it.

Disinfection by Steam.—Dr. Alvah H. Doty, health officer of the port of New York, in an article with this caption in the current number of the *American Journal of Medical Sciences* says: "The certainty of its (steam's) germicidal effect, the rapidity of action and its high penetrating power under proper conditions give it the highest rank. Unfortunately, the cost of apparatus necessary for its proper application limits its use mainly to quarantine and other public services. Although potent when intelligently employed, steam is worthless when improperly applied." The writer thinks that 230 degrees Fahrenheit is needed and an exposure to this heat for fifteen minutes. Then the steam exhauster is to be used to secure the same degree of vacuum. "After the vacuum of twenty inches has been obtained the fresh air inlet is opened and a current of fresh air allowed to pass through the chamber and its contents. This, it must be understood, is in conjunction with the steam exhauster, which is still kept at work. The entrance of the air, of course, breaks the vacuum, but the exhauster carries the air rapidly through the chamber. After an exposure of eight or ten minutes to this treatment the clothing, after being unrolled and exposed for five or six minutes, becomes dry and can be at once worn." To continue our quotation, "it is unsafe to compute too closely the degree of heat necessary for germicidal action; therefore, considerable margin should be allowed. For this reason I believe that a temperature of at least 155 degrees must be secured inside the packages to be disinfected." Dr. Doty believes that the disinfection of ships' cargoes on board the ship is valueless. He says: "I do not believe the low temperature of the hull can possibly be raised to a sufficient degree by the amount of steam which can be thrown into this part of the vessel, taking into consideration the numerous leaks which are always present. Fortunately, the ship's hold and cargo are rarely infected, and are too frequently subjected to a worthless disinfection."

Heavy Sanitary Requisitions at Dublin.—The unfortunate coincidence in that city of three different epidemics, namely, scarlet fever, measles and whooping cough, has rather overstrained the resources of the public health officials and left them and their department open to much unnecessarily harsh criticism. At the annual meeting of the Dublin Sanitary Association the Registrar General stated that according to the returns at that precise date, "the only place that beat Dublin in the height of its death rate was Bombay, which had a mortality of 102 per 1,000." The mayor has recently said in public that the present mortality is largely owing, in his opinion, to poverty and wretchedness among the laboring class in Dublin, brought about by the prolonged building strike of last year. The Dublin Sanitary Association should remember that while Sir Charles Cameron, the medical officer of health, and Mr. Stafford, the medical inspector under the Local Government Board, proposed the establishment last year of a special hospital outside the city for the treatment of infectious disease, the project was strongly and effectively opposed by the Association. The main drainage works are being pressed forward by the corporation with commendable energy, and at an expenditure which will ultimately reach at least one million dollars. An inspection of all the tenement houses has recently been made, while the 5,000 dairy cows in the city have been examined. Circulars have been sent to all the city schools recommending that they should be closed, the corporation not having any power to close them compulsorily or to inflict the money loss on the teachers, which such a measure would entail. Many of the schools have, however, been closed. The private slaughter-houses can not be closed without a considerable expenditure in the shape of compensation. The whole problem is a difficult one, and at bottom to a large extent a question of money. The city rates have gone up by leaps and bounds and are now nine shillings in the pound, and the municipal accounts for 1896, which have just appeared, show that they are likely to become much higher. The cost of the sanitary department rose last year from $105,000 to $118,000. Nearly $40,000 was added to the cost of the cleansing department, which advanced from $200,000 to $240,000; and the sewer rate expended in two of the districts was increased by $25,000. These items may be classed as "sanitary"; and they show in the gross an increase of nearly 20 per cent. The population of Dublin being estimated at 350,000, these expenses represent an outlay of nearly $1.10, per capita.

BOOK NOTICES.

King's College Hospital Reports.—Being the annual report of King's College Hospital and the Medical Department of King's College. Edited by NESTOR TIRARD, M.D., F.R.C.P.; W. WATSON CHEYNE, F.R.C.S.; JOHN PHILLIPS, M.A., M.D., F.R.C.P.; W. D. HALLIBURTON, M.D., F.R.S., Vol. III, Oct. 1, 1895 to Sept. 30, 1896. London: Printed by Adlard & Son, 20 Hanover Square. Price 7s, 6d.

The volume has been delayed owing to the many changes that have taken place in the staff. These changes say the editors "have been very numerous. Shortly after Sir George Johnson's death Dr. Lionel Beale and Dr. Duffin resigned the Joint Professorship of Medicine, and the former was appointed Consulting Physician to the Hospital." Mention of the new appointments follow, and the editors continue, "it is with peculiar gratification that we record here the honor conferred upon the Hospital and upon the profession in the elevation to the peerage of Lord Lister, President of the Royal Society."

The volume opens with a memorial sketch of the life of the late Sir George Johnson, from the *Lancet* of June 13, 1896, and they have appended letters relating to his life containing personal reminiscences not heretofore published. The various scientific papers in the volume are of unusual interest.

Twentieth Century Practice, an International Encyclopœdia of Modern Medical Science by leading authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City in twenty volumes. Vol. XI. Diseases of the Nervous System. Cl. 8vo, pp. 962. New York: Wm. Wood & Co. 1897.

The contributors to this volume are L. Bruns, M.D., Hanover; F. X. Dercum, M.D., Philadelphia: Jas. Hendrie Lloyd, Philadelphia; Chas. K. Mills, M.D., Philadelphia; Paul J. Möbius, M.D., Leipsic; Adolf von Strümpell, M.D., Erlangen, Bavaria; F. Windscheid, M.D., Leipsic; Lightner Witmer, Ph.D., Philadelphia.

The topics have been assigned as follows; "Diseases of the Cerebro-spinal and Sympathetic Nerves," Dr. Lloyd; "Trophoneuroses,"(excluding scleroderma, acromegaly and adiposis dolorosa), Dr. Mills; "Trophoneuroses" (scleroderma, acromegaly and adiposis dolorosa), Dr. Dercum; "Diseases of the Spinal Cord," Dr. Bruns and Dr. Windscheid; "Tabes Dorsalis," Dr. Möbius; "The Combined System Diseases of the Spinal Cord," Strümpell; "Pain," Dr. Witmer. Many of the articles in this volume are of quite as much interest to the surgeon as to the physician, for injuries and tumors [illegible] cord are treated of, their clinical symptoms and diagnoses. On the whole the volume is the best that has yet appeared in the series.

Transactions of the Association of American Physicians. Twelfth Session, held at Washington, D. C., May 4, 5 and 6, 1897. Vol. xii, pp. 510. Philadelphia: Printed for the Association, 1897.

The twelfth annual meeting of this Association was held under the presidency of Dr. J. M. DaCosta of Philadelphia. There are many local medical societies with a larger membership, but there are few that have a larger proportional attendance at the meetings or present papers of higher value. Sixty-seven of the American physicians attended the meeting.

What a Young Boy Ought to Know. By Sylvanus Stall, D.D., etc. Philadelphia: The Vir Publishing Company. 1897.

The reverend author says that when a boy he felt the need of just such a book as this, and as a pastor he again saw its need. Looking over the book from the standpoint of a physician, we can see no objection to it, provided that each parent for himself shall judge of the capacity of his son. Not all boys are docile and teachable enough to profit by such a work, and the question of the stage of mental development at which to begin this instruction must be a matter to be appropriately left to personal judgment.

International Clinics. A quarterly of clinical lectures on Medicine, Neurology, Surgery, Gynecology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology and Dermatology, and specially prepared articles on treatment, by professors and lecturers in the leading medical colleges of the United States, Germany, Austria, France, Great Britain and Canada. Edited by Judson Daland, M.D., of Philadelphia; J. Mitchell Bruce, M.D., F.R.C.P., London, and David W. Finlay, M.D., F.R.C.P., Aberdeen. Vol. ii, seventh series, 1897. Philadelphia: J. B. Lippincott Company. 1897.

There are forty contributors to this volume and all of them are in active practice, and have here presented the clinical appearances, symptoms and suggestions for treatment of an immense variety of cases. The personal observation of cases is naturally the best method of acquiring that knowledge required by the practitioner, and next to personal observation is the printed clinical lectures as reported. It is not surprising to find these volumes in the hands of a very large number of practitioners, and that this quarterly meets the popular demand which we learn is steadily increasing. The volume under consideration is fully equal in point of interest to its predecessors, and is worthy of the same success.

NECROLOGY.

Albert F. E. Krog, M.D., New York University, 1881, died very suddenly of cardiac disease in New York city August 10. A summons found him dead, although he spent Sunday, August 8, in the Catskills and returned, without his wife, somewhat ill on the following day.

James E. Kendall, M.D., Parkersburg, W. Va., August 6, aged 57 years. Dr. Kendall was graduated from Cleveland Medical College in 1861, in 1863 entered the Union service as assistant surgeon Eleventh West Virginia Infantry and was in charge of the army hospitals at Keyser and Parkersburg at the battle of Cloud Mountain. From 1867 he was a member of the State Medical Society (W. Va.) and from 1872 a member of the American Medical Association. In 1881 he was a delegate to the International Medical Association, London, and was for two years city health officer of Parkersburg.

Edgar A. Holmes, M.D., North St. Paul, Minn., August 8, aged 45 years.——E. M. McPherson, M.D., Janesville, Wis., August 12, aged 35 years.——John W. Powell, M.D., Peoria, Ill., August 6, member of Indiana and ex-president of Carroll County (Ind.) medical Societies.——Charles N. Tate, M.D., Alexis, Ala., August 4.——Edgerton Griffin, M.D., Brantford, Ontario, August 7, aged 68 years.——M. J. Oertel, M.D., professor laryngology and rhinology, Munich.——Chudzinski, M.D., professor and preparateur at the Anthropologic Laboratory at Paris; victim to his extreme devotion to science.——Marechal, Brest, aged 64 years, distinguished retired naval medical officer; death from puerperal infection through finger abrasion.——E. Legros, M.D., editor of *Presse Méd. Belge*.——W. Marmé, M.D., Göttingen, professor of materia medica.——W. T. Preyer, M.D., Wiesbaden, ex-professor physiology at Jena.——J. E. Lorenzo, M.D., professor of surgery, Salamanca.——C. Grillenzoni, M.D., ex-professor of anatomy, Ferrara.——Debrou, surgeon at Orleans, France, aged 84 years.——C. Stark, M.D., superintendent asylum, Stephansfeld, Alsace.——J. de Antelo, M.D., professor of pathology, Manila.——J. de Letamendi, M.D., professor of pathology, Madrid.——P. C. Plugge, M.D., professor of pharmacology, Amsterdam.——J. Nathan, M.D., Berlin.——H. Wasserfuhr, M.D., aged 74 years; distinguished for his services in hygiene, etc.——J. A. Steuerhausen, M.D., Frankfurt a.-M.——M. Wilkens, M.D., Vienna, professor in Agricultural College.——Professor Vigneron, Marseilles.

SOCIETY NEWS.

Medical Society of the Missouri Valley.—The annual meeting of the Society will be held at Council Bluffs, Iowa, Sept. 16, 1897.

The Tri-State Medical Association of Alabama, Georgia and Tennessee will hold its annual meeting in Nashville, Tenn., Oct. 12 to 14, 1897.

Medical Society of New Jersey.—Dr. D. C. English, president of the State Medical Socity, has appointed Dr. William Pierson of Orange, N. J., third vice-president to fill the vacancy occasioned by the death of Dr. John J. H. Love; also Dr. William J. Chandler of South Orange recording secretary, in place of Dr. Wm. Pierson, resigned. Dr. Pierson belongs to one of the oldest and most prominent families in New Jersey, and is one of the ablest practitioners in the State. He has for thirty-one years been the efficient secretary of the State Society and was in 1894 elected an honorary member when he declined the office to which Dr. English has just appointed him. His father, Dr. William Pierson, Sr., also served the State Society thirty-one years, when he was elected third vice-president in 1866, and, according to custom, became president in 1869. Dr. Chandler has for many years been one of the most prominent physicians in the State. He graduated at the College of Physicians and Surgeons, New York City, in 1868.

MISCELLANY.

To the Members of the Section on Ophthalmology.—A photogragh of Dr. Baker's case of "Melano-sarcoma of the Conjunctiva" was mislaid at the Philadelphia meeting. It can not be replaced and is desired to illustrate the paper. As it may, inadvertently, have been gathered up with the papers of some member, all are asked to look over such papers and if the photograph is found to return it to Dr. A. R. Baker, Cleveland, Ohio, or to the secretary of that meeting, Dr. Horace M. Starkey, 70 State Street, Chicago.

Hospital Abuse in London.—Dr. Isambard Owen at a recent meeting of the Hospital Reform Association said, that allowing for the possibility of many patients being reckoned twice, no fewer than 500,000 persons received during the past year outdoor relief at the hands of the gerat London hospitals. To these also must be added the large number of cases that had been treated at the smaller hospitals, which would bring the total up to figures quite appalling.

The Moscow Congress.—The Russian medical journals are requesting the profession to hold at the disposal of the Congress cases of exceptional interest that may be observed, as Russian methods and therapeutics are to be exhibited as an incidental feature of the Congress. Four thousand members had been inscribed by the middle of July.

New University College Hospital, London.—The renovated hospital will be nearly three times its present size, built in the form of a diagonal cross so as to obtain the maximum of light, air and accommodation. The work will not be completed for three or four years to come and it is not unlikely that the sum of $600,000 put aside for this purpose will ultimately be exceeded.

Thumb Plastics.—The *Wien. klin. Woch.* of July 15 contains an illustrated article by C. Nicoladoni describing several cases in which he had succeeded in saving the thumb, after traumatism or carbolic gangrene, by transplanting flaps from the breast. He proposes in future cases to attempt to substitute the second toe for the thumb, and shows how this could be accomplished, thus securing a jointed thumb with a nail.

Surgeon General Sternberg in Moscow.—Surgeon-General George M. Sternberg, U. S. Army, is now in Europe to attend the meeting of the International Medical Congress in Moscow. He will present two papers to the Congress, one entitled "The Bacillus Icteroides of Sanarelli (Bacillus X., Sternberg)," the other, "The Radical Cure of Inguinal Hernia in the U. S. Army."

British Medical Association.—Dr. Woodruff, the editorial secretary of the *Ophthalmic Record*, has made arrangements with the Wabash and Canadian Pacific Railroads for a sleeping car from Chicago through to Montreal. It is the intention to leave Chicago from Dearborn station at 3:10 p. m. Sunday, August 29, arriving in Montreal the following evening. Further information can be had by applying to Editorial Secretary, *Ophthalmic Record*, 1102 Reliance Building, Chicago.

Pneumoscope.—The *Deutsche m. Woch.* of July 22 describes the pneumoscope of A. M. Bloch as a wide tube with a partition at the end, fitted with adjustable windows, the space measured off into square millimeters. The nose is held closed and the person breathes through the tube into his mouth. The windows are gradually closed by turning a screw without until breathing becomes difficult. The amount of window space left is the standard for the test.

Medical Men Visit the Hunyadi Janos Springs, Aug. 11, 1897.—The American delegates to the Medical Congress to be held in Moscow, visited the Hunyadi Janos Mineral Springs at Buda Pesth August 11. On this occasion Professor Senn, Chicago, Prof. Daniel R. Brower, Chicago, Dr. Lucy Waite, Chicago, F. M. Lloyd, New York, Prof. G. R. Fowler, Brooklyn, Maj. W. H. Forwood, U. S. Army, Washington, W. F. Southard, editor *Pacific Medical Journal*, and United States Consul at Buda Pesth, Frank Dyer Chester, have made a close inspection of the establishment.

Crystallized Skeletons.—The *Progrès Méd.* reports that two lead coffins were recently exhumed at Paris dating from 1630, in one of which the skeleton was found covered with crystals, the skull forming a magnificent geode. Professor Lacroix states that the crystals are formed of a bicalcic hydrate of phosphate, metabrushite, extremely rare. It is sometimes found in the soil of caves and in the guano of the Antilles. It has twice before been found on skeletons. The crystals in the skull evidently show that the cerebral substance was concerned in this auto-mineralization.

The Paris Medical Faculty announced last year that the courses were so crowded that students from abroad would be obliged to pursue their practical studies in some of the other medical colleges of the country. This, in connection with the restriction that the alien Paris graduate was not allowed to practice in France, reduced the number of foreign students from 1,046 in 1895 to 657 last year, and it was found that the other medical colleges in the country did not gain by this system of exclusion, as the foreigners passed them by to enter at Berlin, Vienna, Leipsic, etc., on account of the prestige of the larger universities. The Paris authorities will probably soon suspend their restrictions on the foreigners, retaining only the regulation that graduation at Paris does not confer upon a foreign student the right to practice in France.

Improved Doyen Cutters for Removal of Uterine Tumors, Vaginal Hysterectomy.—Much time is lost by the necessity of constantly removing Doyen's cutting tubes to empty them, in extirpating a tumor of the uterus by tunnelization as practiced by Pran, Doyen, and others. To remedy this, Ingianno makes the tube with openings, and a crescent shaped, spirally curved knife inside turned by a handle without. As this bores into the tumor the tissues cut out by it emerge in a spiral through the openings in the tube, and the boring can be continued indefinitely. Prof. Acconci endorses the improved cutter as a much needed improvement and time-saver.—*Gazetta degli Osp. e delle Clin.* June 13.

Involuntary Hypnotism.—Professor Desplats observes that many inexplicable neurotic and mental conditions may be due to involuntary auto hypnotism and describes several convincing examples in the *Journal des Sc. Méd. de Lille*, July. One young man was hypnotized by the sight of a pair of shining scissors or the revolving wheels of a bicycle, and committed numerous extraordinary actions while in this unsuspected condition. Another was hypnotized whenever he met the eye of a certain comrade, which rendered life so unendurable for each of them that they separated to distant cities. He warns against the dangers of hypnotism practiced in sport, as it leads to such susceptibility that the most serious results may follow later.

France Behind in the Making of Spectacles—When L. Borsch (formerly of Chicago, now Paris) presented his bifocal glasses at the recent Congress of the French Society of Ophthalmology he stated that the distance from each pupil should be measured separately and the bridge adapted to the shape of the nose. M. Parent remarked: "We are far behind in the making of spectacles in France. We ought to insist upon it that our opticians make all their glasses by special measurements, but this is not done." The peculiarity of the bifocal glasses is that a different kind of glass is used for each eye; crown and flint. Owing to their different refraction, one glass will focus at 10 D. and the other at 15 D., for instance, with the same curve.

Favorable Effect of Koch's T.R. on Lupus.—The *Deutsche med. Woch.*, of July 8 and 22, also the *Therap. Woch.*, of July 18, contain reports of numerous cases treated with the new tuberculin. The expense is considerable. Prof. Lassar found it to cost 17 marks a day for his patients. Schultze found that a complicating pleuritis sicca was much improved and a perichondritis of the arytenoid cartilage cured during the treatment. The effect on pulmonary tuberculosis is still dubious, but it seems to affect lupus most favorably. Even in old rebellious cases the ulcerations and infiltrations disappear (Bussenius, 3 cases). Seeligmann reports a chronic case of genital and cutaneous tuberculosis that is far on the road to complete recovery; Wörner two cases of lupus remarkably improved, and two others that were treated after operation, which have been protected from relapse. But his most remarkable success was in a scrofuloderma that had resisted all treatment for eleven years. Two report extremely violent reaction following the use of T.R., bearing the date of June 11, and Bussenius noted the same whenever the maximal dose was administered in all but four of his nineteen cases. In the case of one child serious collapse occurred twenty-two hours after the twenty-third injection of one-third the dose suggested by Koch. Others seemed to bear the injections without disturbance. Bussenius states that in his 334 injections no abscesses occurred, and bacteriologic tests of the tuberculin failed to disclose the presence of pyogenic germs at any time.

Experimental Injections of Salt Solution in Strychnin and Diphtheria Intoxication.—Roger finds that small injections have no effect, but that larger amounts injected subcutaneously (164 to 228 c.c. salt solution per kilogram), enable rabbits to resist strychnin intoxication much better than the control animals. But this effect is changed to its opposite, an increased susceptibility to the poison if the latter is injected directly into the veins. Chassevant and Got also report the favorable effect of intravenous injections of salt solution in attenuating the intoxication from strychnin in rabbits, but not in dogs. They suggest that possibly the bulbus is protected by the hydremia, and elimination of the poison through the kidneys favored. Enriquez and Hallion, on the other hand, report an injurious effect from intravenous injections of salt solution in experimental diptheritic intoxication, whether the toxin is injected directly into the blood or subcutaneously.—*Cbl. f. Phys.*, from *C. R. Soc. de Biol.*

Sciatica Cured by "Hersage."—First proposed by Delagenière to remove the venous varicosities assumed to be the cause of the pain, it was found that no true varicosities existed, but that the operation it itself cured the sciatica. It consists in merely loosening up the fibers of the nerve trunk with a blunt instrument (harrowing). After chloroform, the nerve trunk is exposed and with the tip of a grooved sound, the fibers are separated for a couple of centimeters, broadening and flattening it; drainage and suture. The patient at first experiences some pain in the nerve, and numbness in the limb, but as sensibility returns the neuralgia is found definitely cured. Experimental research shows that "hersage" of the sciatica produces transient insensibility of the nerve, while preserving its motility. It is suggested that the operation might relieve neuralgia in other nerve trunks. The two cases reported cured in the *Semaine Méd.*, of July 14 were old obstinate sciatica, resisting all other treatment; one a woman of 37, the other a man 45 years old.

Commitment of Connecticut Insane Paupers.—A Connecticut statute provides that when any pauper in any town shall be insane, a selectman of such town may apply to the court of probate of the district wherein such pauper resides for his commitment to the State hospital for the insane; and that, if so committed, $2.50 a week of the expenses of his support shall be paid by the town legally chargeable with his support. Under this provision, the supreme court of errors of Connecticut holds, in the case of the Connecticut Hospital for the Insane v. Town of Bridgewater, reported in 36 *Atlantic Reporter* 1017, that any pauper who is found in any town in a state of insanity is a proper subject of such an application by a selectman of that town. It is of no consequence, the court says, whether he has been there an hour or a year. If he be, in fact, in the town, in a state of insanity, he resides there for the time being, within the meaning of the statute. The object of the proceeding is to put the pauper, as soon as possible, into a hospital where he can secure proper care and treatment.

Sufficient Complaint in Malpractice Case.—The complaint in Crowty v. Stewart alleged that the plaintiff was kicked on the right leg by a vicious horse, and the same thereby broken and greatly injured. That, at that time, he called the defendant, a surgeon, and informed him of the manner of receiving such injury and employed him, as such surgeon, to examine such broken leg and ascertain the extent of the injury thereby caused, and to set the same, if broken, and to treat and heal the same, for whatever the injury was to it. That for that purpose the defendant undertook, as a surgeon, to examine the injured leg to ascertain whether the same was broken and also undertook to treat and heal it for whatever the injury to it was. That pursuant to said undertaking the defendant examined the leg in a negligent and unskilful manner, and failed to ascertain that the same was broken, or the extent of the injury to it, and treated and tried to heal the leg as though it was not broken, greatly to the plaintiff's injury, making him sick, causing him much pain and annoyance, and putting him to great expense, etc. The sufficiency of this complaint was demurred to, but the supreme court of Wisconsin holds that it contained in substance the averment which it has declared to be necessary in a malpractice case, and was entirely sufficient.

Etiology of Cancer of the Uterus.—Baecker contributes a study of 705 cases of cancer of the uterus to the *Arch. f. Gyn.*, liii, 1, observed at Buda Pesth. He denies a parasitic etiology and ascribes the origin to puerperal endometritis, as few nulliparæ are affected by it (61 in 705), while the nulliparæ furnish a fourth of the non-cancerous gynecologic affections. He excludes also gonorrheic origin, as gonorrhea is rare among women with cancer, and prostitutes, who are so frequently affected with gonorrhea, rarely have cancer. He explains the fact often noted that cancer of the uterus is so much more frequent among the poor, as due to lack of medical treatment of the endometritis. His experience has been that the cancer is located higher as the patient is more advanced in years, which corresponds to our knowledge of the localization of endometritis at different ages. His conclusion is therefore that no case of chronic endometritis should be neglected, and an examination should be made in every case of whites or hemorrhage, especially at the critical age.—*Sem. Méd.* July 21.

Something Like Civil Service for Indiana Institutions.—By an Indiana statute the office of trustee and the board of control of the Central Hospital for the Insane, for the Northern Hospital for the Insane, for the Southern Hospital for the Insane, for the Eastern Hospital for the Insane, for the Indiana Institution for the Education of the Blind, and for the Institution for the Education of the Deaf and Dumb, was abolished, and the control, government, management and general supervision of such institutions was vested in a board of three trustees for each of them, to be appointed by the governor, not more than two of whom shall belong to the same political party. In the employment of superintendents, and confirmation of assistants and other employes, it is further provided, said boards shall take into consideration only the qualifications and fitness of the persons selected to fill such places, and no person shall be selected or employed to fill any of such positions on account of his political belief or affiliations, and no superintendent, assistant or employe shall be dismissed from service on account of his political belief, faith or affiliations.

Who may Attend Physical Examination of Female Plaintiff.—Section 873 of the New York Code of Civil Procedure provides that, where the plaintiff in a personal injury case is a female, she shall be entitled to have such physical examination as the court may in its discretion order before physicians or surgeons of her own sex. Besides the female plaintiff, the general term of the city court of New York holds, Lawrence v. Samuels, there may be present the female physician appointed by the court, and a female physician to represent the interest of each of the parties in litigation, and such other females as the plaintiff may desire. But the court denies that, in such an examination, the plaintiff's counsel has the right to bring whom he pleases, of the male sex, to witness his client unclothe and expose herself. The law never intended, it declares, that the attorney or any male should appear or take part in any such physical examination. He may be present, however, at the oral examination of the physician thereafter. The physician appointed is an officer of the court, and subject to directions of the same, and to its orders, and should be sworn.

"Fake" Surgery at Paris.—The *New York Sun* correspondent at Paris is responsible for the following statement regarding a rampant condition of quackery in that city. He says that irregular practice has come to be more profitable than the legitimate practice of medicine with a large class in Paris. The other day a gentlemen whose rooms are crowded from morning till night with patients, was threatened with prosecution for exercising the profession without a diploma. Being thus brought to bay, he confidentially displayed to the officials the necessary document. He, however, implored the authorities to keep the diploma secret, explaining that if his clients had an inkling that he was a veritable physician his gains would diminish. M. Paul de Cassagnac makes even a more remarkable disclosure and vouches for its authenticity. He asserts that there is a house in Paris in which patients are received for the purposes of undergoing sham operations. They have been induced to believe that they are suffering from some organic complaint which can only be cured with the knife, and they betake themselves to this establishment, which has been particularly recommended to them. On the day appointed for the so called operation they are put under chloroform and a few make-believe cuts and scratches are inflicted. In certain medical cirles there is a regular name for men who practice these tricks on the victims of imaginary ailment.

A Railway Hospital Car.—One of the Belgian railway companies has instituted what is called "the hospital car," which is designed to serve a twofold purpose. The first of this kind of car went into commission in the latter part of April. In the event of a serious railroad accident the car may be run to the spot where the wounded may be picked up and carried to the nearest large city for treatment, instead of being left to pass long hours in some wayside station while awaiting surgical attendance. It also enables the railway companies, at certain seasons or upon special occasions, to transport large numbers of invalids to health resorts or places of pilgrimage. The interior is divided into a main compartment, a corridor on one side and two small rooms at the end. The largest compartment is the hospital proper; it contains twenty-four isolated beds on steel tubes hung on powerful springs. Each patient lies in front of two little windows, which may be closed or opened at will. Each bed is provided with a little movable table and a cord serves to hold all the various small objects which the patient may need. The corridor on the outside of the hospital chamber leads to the linen closet and the doctor's apartment. In the latter is a large cupboard. The upper portion is used for drugs; the lower part is divided into two smaller compartments—one serving as a case for surgical instruments, the other as a receptacle for the doctor's folding bed. The hospital compartment is carpeted with linoleum or other material to deaden the sound of walking. Various trapdoors in the floor, when opened, disclose to view an ice chest, a compartment for the disinfection of soiled linen, and a provision cellar. If necessary, a portion of the hospital chamber may be transformed into an operating room for urgent cases.—*Consular Reports.*

Dr. Nansen on the Prevention of Scurvy.—Dr. Nansen, in his lecture at Albert Hall on "Some Results of the Norwegian Arctic Expedition," among other highly interesting matters, touched upon one of great medical interest. We all know the great difficulty that has been experienced and has always to be encountered on such expeditions, and frequently in those of a military nature, in regard to scurvy, a malady which has hitherto been found to occur in Arctic explorations. Dr. Nansen ventured to declare that it was very easy to avoid that disease by taking the proper precautions, and he proceeded to relate his experience: "Dr. Torup, Professor of Physiology at the University of Christiania, had come to the conclusion, after examining the subject, that scurvy must arise from poisoning, caused in particular by badly preserved meat and fish. He thought that in the decomposition which takes place in the meat from bad preserving, in salt meat, for instance, there was poisonous matter allied to the so-called ptomains, which when constantly partaken of, engendered the malady we call scurvy. Particular attention was paid to this at the time of their equipment and from their experience and the investigations he had the opportunity of making during the journey, he could entirely subscribe to Torup's opinion in this matter. It was to be hoped that in the near future there would be scientific elucidation of this important point; and it was equally to be hoped that certain means for avoiding this hithertò so fateful sickness might be shown." Whether this supplies a key to the explanation of all the outbreaks of scurvy that have occurred it would be premature to declare; but it marks a new departure and is well worthy of further investigation. Meanwhile we think it may possibly account for some of the outbreaks about which a difference of opinion existed as to whether they were to be entirely explained by the absence of fresh vegetables. At a dinner given in his honor by the Savage Club in London, Dr. Nansen spoke of the great difficulties encountered by his expedition in maintaining personal cleanliness. "We did our best to keep ourselves clean," he said, "and tried all sorts of different ways. We tried the Esquimaux way, but that was no good. What we had to do was to use the knife and scrape ourselves. The Esquimaux method is that of preserving all the urine secreted by the members of the establishment and using it for all purposes of domestic and personal cleanliness.

Extravasation of Urine.—Mr. Richard Barwell related before the Clinical Society of London a remarkable case of extravasation of urine in a man aged 36 years, who previously to Nov. 24, 1896, was perfectly healthy. On that night, after coitus, in which nothing unusual occurred, he went to sleep, and on waking the next morning he found the scrotum much swollen. During the next few days the swelling increased. On the 29th, Mr. Barwell saw the patient in consultation. He had a subnormal temperature and a rather feeble, quick pulse, 108; the tongue was slightly furred and the constitutional symptoms were slight, and he said he felt quite well up to "four hours ago," and even now only "a little down." The scrotum was greatly distended, boggy to the touch, red, and studded with blotches here and there and dark brown discoloration; the penis was but slightly swollen and reddened and free from sloughy spots; the perineum was much distended to within a very short distance of the anus, and exhibited two sphacelated spots. He asserted that he never had any difficulty in passing urine, which flowed in a full size stream. Mr. Barwell made deep incisions into the perineum and scrotum, exposing the superficial muscles of the urethra and the testicles. The sodden tissues were full of urine with the usual ammoniacal, sloughy odor. One bleeding vessel, being too rotten to bear either torsion or ligature, was secured by leaving on it a pair of forceps; the very soft state of all tissues rendered interference with the urethra unadvisable. Five days after the incisions were made the patient lost about four ounces of blood by the rupture of a vessel in or close to the right testicle. This depressed his health considerably, but freer stimulation overcame the condition in about eight hours. The rare and interesting features of this case lie in the local condition. Rupture of the urethra as the immediate result of coitus has once or twice been reported, but invariably in the penile portion of the tube, never, so far as Mr. Barwell was aware, in the membranous part. A No. 12 catheter passed into the bladder without encountering the slightest obstacle, and the treatment for stricture of the urethra was therefore unnecessary. The man lost by sphacelus about four-fifths of the scrotum, but the parts healed and the whole was quite sound exactly six weeks after, the testicles being enclosed in a new bag which, though it looked tight, interfered neither with comfort nor function.—London *Lancet.*

Societies.

We note the following meetings:

Illinois—Adams County Medical Society, Quincy, August 9. The Carroll County Medical Society has been organized by the physicians of Savanna and Thompson.

Indiana—Vigo Medical Society, Terre Haute, August 5.

Iowa—Austin Flint Medical Association, Clear Lake July 31. Polk County Medical Society, Des Moines, August 3.

Michigan—Barry and Eaton Medical Association, Charlotte, July 29.

Minnesota—Southern Minnesota Medical Association, Winona, August 9.

Missouri—Seventh annual meeting of the Central District Medical Society, Sedalia, August 5.

New York—Medical Society of Steuben County, Hornellsville, August 8.

Ohio—Logan County Medical Society, Bellefontaine, August 6. Morrow County Medical Society, Cardington, August 2. Union Medical Association, Lisbon, August 12.

Pennsylvania—Seventeenth annual meeting of the Lehigh Valley Medical Association, Water Gap, July 28. Luzerne County Medical Society, Wilkesbarre, August 8.

Wisconsin—Central Wisconsin Medical Society will meet in Baraboo, September 28.

Hospitals.

The New Surgical Service of the Hôpital Broca-Pascal, Paris, is a one-story building, lighted from above, ensuring abundance of light, electric ventilators with special air shafts and chimney, steam-heated, tiled floors, iron furniture, Herbet beds, laboratory, photographic and electrotherapeutic rooms, besides the usual rooms for dressings, etc. One operating room is reserved for laparotomies, the other for general operations. The two wards contain one twelve and the other eight beds, with six single bedrooms for isolation, all communicating, to reduce the number of attendants necessary. In the center of each room is a large, specially-devised case with glass walls, so that its contents can be seen from without. There are an unusual number of bathrooms, washstands, etc., and the walls are to be attractively frescoed, with pictures in the corridors. A charity fund was founded in 1894, amounting now to 50,000 francs, of which a fifth has been distributed to needy patients in the service, paying arrears of rent, supporting their families, supplying clothing or railroad fare for them to return to their country home, etc. The fund is administered by a committee of lady patronesses. The service owes its improved quarters to the indefatigable efforts of Pozzi, "the man who has done the most for gynecology in France." He considered he had accomplished a great deal when, in 1885, he secured the introduction of a single water faucet into the miserable barracks that sheltered the surgical service at that time. The pavilion also contains a small suite for a syphilitic maternity with an eight-bed ward, two isolating rooms and a work room.

Cincinnati.

The Presbyterian Hospital for Women is making a much needed addition to the institution. Mr. Alexander MacDonald, the Standard Oil magnate, has donated $25,000 to make the improvement.

The Board of Trustees of the Cincinnati Hospital has under consideration the advisability of reducing the number of physicians on the visiting staff.

THE PUBLIC SERVICE.

Army Changes. *Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from August 7 to 13, 1897.*

Capt. William H. Arthur, Asst. Surgeon (Ft. Myer, Va.), is granted leave of absence for one month, to take effect about Sept. 1, 1897.

PAMPHLETS RECEIVED.

Armuaire de l'Ecole de Méd. et de Chir. de Montreal, 1897-98.

Antivivisection papers. Boston: N. E. Antivivisection Society.

Bellevue Hospital Medical College, New York City. Announcement fo 1897-98.

Case of Hermaphrodism; Description of Specimens taken from a Hermaphrodite. By Carl Beck, M.D., illustrated. Paper reprints from Medical Record.

Civic Duties and Responsibilities of the Physician to his Community, State and Nation, The. By John Punton, M.D. Paper, 10 pages. Reprinted from Alienist and Neurologist.

MILITARY SURGERY IN GREECE.

BY N. SENN, M.D., Ph.D., LL.D.
SURGEON-GENERAL OF ILLINOIS N. G.
CHICAGO.

The war between Greece and Turkey is ended. It was a short and in many respects a remarkable combat. After six or seven conflicts little Greece was conquered by an overpowering foe. In a little more than a month the little kingdom found itself trampled under the feet of a fanatic and greedy conqueror. Fate was against Greece from the beginning of the conflict. The scanty resources of the country made it impossible to maintain an army upon a modern war footing and its citizens, the descendants of the proud and warlike Hellenes, are no longer the equals of their forefathers whose daring exploits and victories have been immortalized in prose and poetry. Centuries of subjugation to foreign power and policies have resulted in a loss of confidence and a diminution in the intrinsic resisting power of the nation that once, under the leadership of great statesmen and warriors, constituted the central power in Southern Europe. When Greece found herself confronted by a war with its envious and bloodthirsty neighbor, she discovered too late the lack of a well disciplined and well equipped army and navy. The first call to arms brought an army into the field of less than 60,000 men. Second-hand guns (Gras) bought from the French government were the arms used. Ammunition was scarce and frequently beyond reach when most needed. According to the testimony of all who were in the field, the Greek soldiers behaved heroically. The quick and complete defeat is evidently attributable more to defective leadership than a want of valor on the part of the troops. The campaign was badly planned by those who were in power and the first defeat resulted in a loss of confidence which was never restored. Turkey rapidly mobilized a well organized and splendidly equipped army of at least 100,000 men along the Grecian border, which at once assumed decidedly aggressive operations. The first battle was fought April 14, the last at Domoko, May 17. The great powers watched the unequal struggle with intense interest, and when it became evident that a complete annihilation of the Greek army was only a matter of a few days, they stepped forward and rendered valuable service by dictating the terms of peace. The Sultan has now to deal with the great powers in adjusting his claims against a conquered and humiliated country. The arms are stacked and the two armies are facing each other almost within speaking distance until the treaty is signed, when they will be withdrawn, and peace, at least for the time being, will be restored. Upon their return the Turks will sing the praises of victory, while the Greeks will bring sorrow and disappointment to their unhappy homes.

During my visit in Patras and Athens I have made faithful attempts to obtain reliable information concerning the treatment and transportation of the wounded on the Greek side. I visited all of the military hospitals and interviewed many military and medical officers and nurses, but the reports received and the statements made were often so conflicting that I find it exceedingly difficult to write upon an authoritative basis. I shall harmonize the facts elicited as much as possible in preparing this report.

Transportation of wounded.—From what I could learn from different sources, the Greek army had few ambulances. The simplest kind of litters were used in conveying the wounded from the fighting line to the dressing station, Two-wheeled carts and donkeys were employed largely in transporting the wounded and sick to the field hospitals. As soon as possible the sick and wounded were conveyed to the nearest landing station and from thence by boat to the hospitals at Athens and Patras. It appears that the wounded bore the rough methods of transportation with great patience and fortitude.

Hospitals.—Germany and Russia sent field-hospitals, which proved of the greatest value during the short campaign. The large military hospitals in Patras and Athens were soon filled and additional room had to be secured for the rapidly increasing number of sick and wounded. In Athens the two military schools and Polytechnicum were transferred into temporary hospitals with accommodations for at least 700 patients. All of the hospitals were found in excellent order, comfortable beds and well-ventilated wards and rooms. The patients receive substantial nutritious food and a liberal allowance of native wine. In one of the hospitals I found twelve wounded Turkish prisoners who received, if anything, better attention than their former enemies. The hospital provided each one of the prisoners with eight cigarettes a day. The prisoners are model patients, but notwithstanding that they are treated with the utmost kindness they are anxious to return to their native land.

Medical officers.—Greece has more doctors to its population than any other country in the world. On an average, two thousand medical students attend the University at Athens annually. Five years is the time required to prepare the student for graduation. Doctors in Greece lead a life of leisure owing to the salubrity of the climate and the overcrowding of the profession. When the war broke out Greece could furnish doctors in abundance, hence the numerous applications of volunteer doctors from the different countries far and near were as a rule declined with thanks. Among the few foreign doctors who did service for the Red Cross Association must be mentioned Abbot, Moffat and Osborne of England. Dr. Abbot performed a number of operations and is highly esteemed by his Greek colleagues. Dr. Skoufas is the Surgeon-General of the Greek army, with the rank of Colonel. He has served in this capacity for two years and during the campaign just ended was busy in his office daily, from 8 A.M. until 2 to 3 o'clock in the morning. He shows the effect of overwork at the present time. He is a most genial gentleman and did every thing in his power to further my object during my sojourn in Athens. He detailed Lieutenant Schultze, a member of his staff, to conduct Col. Forwood of the U. S. Army, Dr. Fowler of Brooklyn and the writer through all of the military hospitals in the city. Prof. Galvani of the University did service in Thessaly. He is the most persistent and ablest surgeon in Greece. He has charge of the Evangelismos Hospital, where he operates daily at 10 A.M. A number of our party, among them Dr. Lucy Waite of Chicago, and Dr. Southard of San Francisco, witnessed two of his operations, one ovariotomy and an amputation of the leg for advanced tuberculosis of the knee-joint. His conveniences for carrying out antiseptic details are limited and yet his results are said to be remarkable. He is a conscientious and pains-taking operator. Among the other prominent physicians of Athens must be mentioned Dr. Savas, the physician of the Crown Princess, and Dr. Kalopothakés, the first female physician in Greece, both of whom have done excellent service in the medical department of the army. The medical officers in the army are distinguished from the line officers by the color of the velvet on the collar of the uniform, which is a dark purple. The surgeons wear side arms and spurs in the hospitals and streets:

Graduates who desire to enter the army must study an additional year and are then commissioned after passing a satisfactory competitive examination.

Hospital corps.—The Greek army has three thousand soldiers who are instructed to serve as litter-bearers and render the first aid to the wounded, but of these only 300 are non-combatants, the remainder being detailed for special duty as emergencies arise. Before I received this information I was astonished to find the entrance of every military hospital guarded by a soldier wearing the brassard and handling at the same time a Gras gun with bayonet fixed.

Red Cross.—The Red Cross Association of different countries did much to relieve the immediate wants of the sick and wounded. England and Denmark sent quite a number of well-trained nurses who did most efficient work in the field and city hospitals. The nursing in the Polytechnicum is performed exclusively by native female nurses. On my arrival in Athens I met two English nurses who had just returned from the seat of war and who were to return home next day. From them I obtained much valuable information regarding the worth of the Red Cross Association. They were Miss C. E. F. Bull and Miss Isabel Carter of Brighton. I requested them to give me some of their experiences in writing which was very promptly done by Miss Bull. It will be of interest to read in her own words a description of the retreat from Larissa.

"Being in Athens when rumors of war between Turkey and Greece were spread, I offered my services to the Greek Red Cross Society as a volunteer nurse for the front.

"On April 13 the first party of six English Red Cross nurses arrived with Mrs. Chant, and the following morning I received a command from H. R. H. the Crown Princess to go to the palace. There I found the English sisters, and was asked by H. R. H. *to accompany* herself and three of the sisters to Larissa, it having been arranged that two should remain at the Greek Red Cross hospital at Volo and that one should accompany Mrs. Chant to Crete.

"We arrived at Larissa on Easter Sunday and were taken around to see all the hospitals. At first we found it very difficult to get a footing in any of them, for the Greek doctors did not like the idea of female help. However, we installed ourselves in the theater of the military hospital, which was overcrowded with untrained orderlies, doctors *off duty*, wounded men *waiting* to be attended to; in fact, a crowd of useless individuals falling in each other's way and hindering the work of two or three really good military doctors who were trying to work. At last the value of the English sisters was discovered and by degrees the room was cleared, and we found ourselves hard at work in the operating theater with two clever *young surgeons* who, we were thankful to find, kept a most strict régime as far as antiseptic treatment was concerned.

"The wounded were brought straight down from the field on mules or in rough wagons. Very little attention could be paid to them in the wards, but when we got a few spare moments we did our best to find out those who were the most severely wounded and had them brought to the theater as soon as possible. Comfort for the poor fellows was out of the question, and it was with the greatest difficulty that a drink of milk could be got for a dying man who was craving for it. Our work was the same from morning till night, and lasted from Easter Sunday until the following Friday night. On the Thursday we had put up a model hospital of twenty beds which had been provided by H. R. H. the Crown Princess. *Everything was in readiness for patients who were too badly* wounded to be moved on to Volo, and we were to have received them on Saturday morning, but alas! the Turks had only to march in and find everything in readiness for *them!*

"On Friday night we retired at 11 o'clock, tired as usual after our day's work. The only thing we remarked was that the firing being very much nearer, the Turks were not far off; however, that did not make much impression on us, for we had been sleeping amid the boom of the cannon for the last six days.

"At midnight our hostess burst into our room crying out, 'Fly for your lives, the Turks are coming into Larissa!' We did not believe it, and when dressed I went over to the Crown Prince's headquarters to learn the truth. I was told that there *was no occasion to fear, and on my return the sisters returned* to their beds. We were not left quiet for long, for soon both host and hostess informed us that they were going, and carried out their intention by leaving the house and locking the doors after them; so that in one sense of the word we were prisoners. At about 2 A.M. a wagon under military escort was brought round, and in spite of any wish of our own to remain we were hoisted up on top of our kit bags and taken down to the railway station, which was surrounded by a panic-stricken crowd waiting for the first train to start, and expecting the Turks to swoop down upon them at the first dawn of day.

"All the wounded from the military hospitals were placed in the train, and to our lot fell standing room in a horse box.

"We left Volo on Saturday evening with the wounded on board the *Thessaly*, and arrived in Athens at 1 A.M. on Monday.

"On Tuesday I left for Arta Caravassera with a Greek lady and three English sisters. On the Epirus side we all settled down to steady hard work under a most clever and able surgeon, Mr. Zainie of the Greek Red Cross.

"CATH. E. F. BULL.

"July 26, 1897."

Only a few of the foreign nurses remain at the present time. I found a Danish nurse at the Polytechnicum and Miss Morris of Manchester, England, in one of the military hospitals. The German Red Cross Association was represented by von Reichenbach of Munich, who brought with him a large supply of medicines and dressing materials. Most all of the dressing material in the different hospitals is of German manufacture. Many of the rich Greeks living in foreign countries sent money, nurses and hospital supplies, which did much to alleviate the sufferings of the victims of the late war. A wealthy lady who lives in Marseilles endowed and maintained a large ward in one of the temporary military hospitals in Athens. The impression prevails on this side that the Turks did not respect the Red Cross, that the wounded prisoners were often tortured and mutilated, especially in the interior of Thessaly, where their conduct could not be watched by representatives of foreign countries. On the other hand, it is asserted that the Greek insurgents abused the privileges of the Red Cross, which angered the Turks, who in turn resorted to revenge by ignoring the Red Cross protection.

Turkish projectiles.—The Turko-Grecian war was characterized by an immense waste of ammunition. The wounds on the Greek side show evidences that the firing was done at great distances. It is related that as a rule the shooting commenced as soon as the enemy came into view. Capt. Dorst of the U. S. Army tells of a little incident which shows how reckless the troops were in the use of ammunition. The Turkish commander sent out about twelve cavalrymen as scouts to determine the position and strength of the enemy. As soon as the men came into view one of the Greek soldiers more than a mile distant opened fire, and in less than a minute firing was heard all along the line at a safe distance from the Turks. The scouts had no difficulty in reporting to their commander the exact location and probable strength of the enemy without coming within reach of the Greek guns. According to all accounts the marksmanship on both sides was exceedingly poor. The Greeks used the Gras gun with a forty-five caliber bullet of lead as the projectile. The Turks used the Martini single breech-loading rifle with a bullet of the same caliber and material. A single Turkish brigade was armed with the Mauser gun of small caliber and jacketed bullets. The Greek military surgeons say that many of the wounds which they saw were small and presented all the appearances of having been inflicted with a projectile of small caliber. All of the bullets which I saw in the military hospitals of Athens were large bullets of lead, evidently the ammunition for the Martini rifle. Miss Morris, the English nurse, informed me that she saw two bullets of small caliber metal-jacketed removed in the field hospitals. In both instances the bullet was removed from a flesh wound of the leg. In neither case was the bullet depressed. It is evident that the injuries were received at a great distance from the enemy or that the force of the bullets was diminished by striking a medium between the contending forces. I saw a number of injuries inflicted by the contents of exploding shells. In one instance the missile was a small round bullet of lead of about thirty-two caliber.

The Greek soldier.—The Greek people are almost proverbial for their honesty, modesty and simplicity of habits. The Greek laborer is generally industrious, strongly attached to his family and anxious to provide for his children a good education equal, if not superior, to the peasantry of any of the other countries in Europe. Theft and premeditated murder are almost unknown. Murder is not infrequent but when committed it is the result of a quarrel, a sudden excitement of passion. Drunkenness does not exist in Greece. Old and young, rich and poor drink a moderate amount of native wine, but the favorite national drinks are coffee and water. The cafetiers and water-venders do a thriving business in restaurants and public places. Cigarette smoking is common, but the use of tobacco in any other form is exceptional. The temperate eating and drinking in Greece has created a typical race

The ordinary Greek is below our average size without an ounce of superfluous fat, muscular and well calculated to do excellent service in a short active campaign. There can be no question that the excellent results which have followed the often imperfect treatment of the wounded during the late war are largely due to the unvitiated, vigorous constitutions of the patients. The uniform and equipment of the Greek soldier are of the simplest and cheapest kind. All efforts at display are lacking.

Woman soldiers.—Three Greek women have become famous during the war just ended. Conspicuous among them is Katarina, who joined the insurgents with her brother, did brave work, was wounded and was brought to one of the field-hospitals for treatment. The illustration shows her upon the cot in the hospital surrounded by nurses. Another woman did similar service with her brother. A third woman carried water to the wounded in the firing line, received several wounds, one of which made amputation of the arm necessary. She died eventually from the effects of the injuries.

THE GREEK SOLDIER.

First dressing.—The many wonderful recoveries from serious gunshot injuries which came under my own observation seem to prove that great pains were taken to prevent infection on the field and later in the hospitals. A representative of the staff of the Surgeon-General informed me that the wounds received early attention. The instructions were to shave the injured part, rub thoroughly with a solution of corrosive sublimate, dust the wound with iodoform and dress with antiseptic gauze. Wire splints were used mostly for immobilizing fractured extremities. In the hospitals plaster-of-paris was used to some extent for the same purpose. Diagnosis tags were not used, consequently many p [illegible] removed unnecessarily, and I have no doubt in some instances to the detriment of the patient. All the primary dressings were applied by the military surgeons; the hospital corps were not expected to take an important part in this work, serving simply as assistants to the surgeons. Elastic constriction and antiseptic tamponade for the purpose of arresting hemorrhage on the field appear to have had only a limited application. One of the nurses whom I met expressed her belief that many lives could have been saved if more attention had been paid to this part of first aid to the wounded.

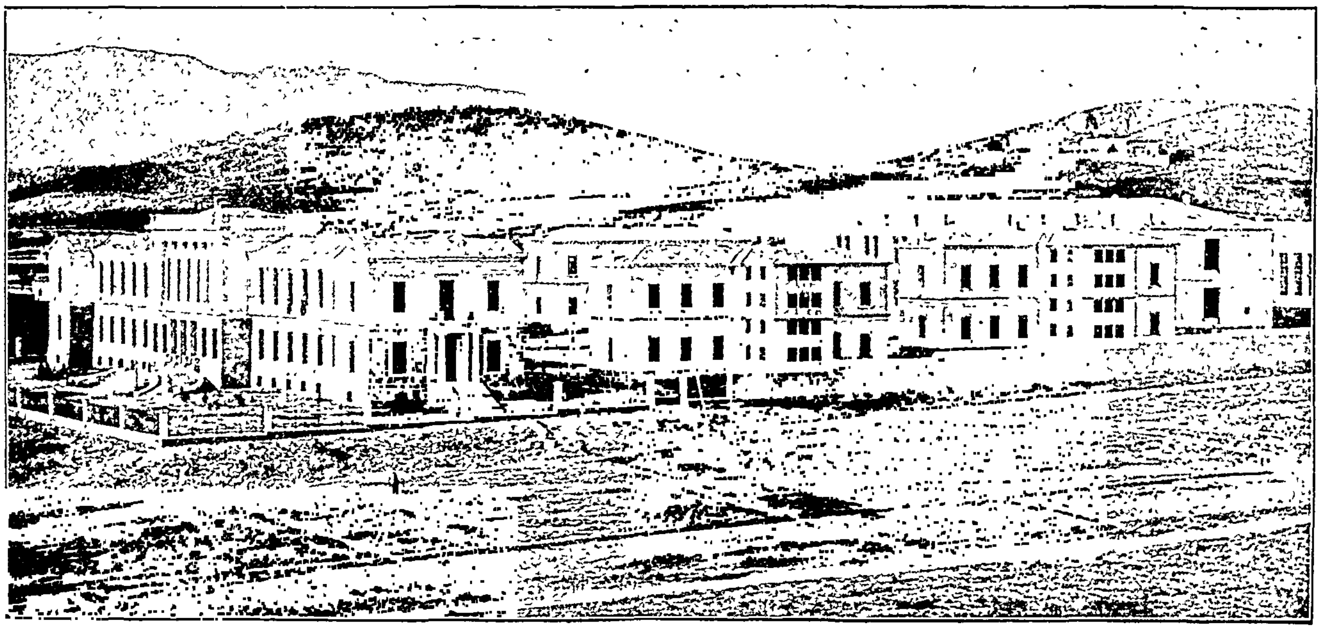
Operations.—Chloroform was used exclusively as an anesthetic without a single death that could have been attributed to this source. A number of amputations were made in the field-hospitals, but few if any primary resections. Secondary hemorrhage appears to have the been very infrequent, undoubtedly owing to the aseptic conditions of most wounds. More or less rigid antiseptic precautions were always carried out, which explains the rapid handling of most of the operative wounds. The instrument supply was simple and obtained almost exclusively of French manufacturers.

KATARINA, THE GREEK AMAZON.

Bullet wounds and results of treatment.—I found it impossible to ascertain even approximate data concerning the number of killed and wounded on either side. The statements made by different persons are so at variance that it is impossible at the present time to estimate the loss of the Greek army. A lieutenant of the Greek army had ready figures claiming that the Greeks killed and wounded 50,000 Turks, while the Greek loss was 15,000. From the observations made in the different hospitals it is more than probable that the number of wounded on the Greek side did not exceed 3,000. Many of these wounds were slight and either did not disable the soldiers or they recovered from the injuries in a few days and returned to their regiments for duty. In no instance was a primary laparotomy performed for penetrating wounds of the abdomen. Dr. Socrate Sp. Tsakona, Prof. Galvani's assistant, informed me that he saw in the Evangelismos Hospital two patients recover from penetrating wounds of the abdomen. In both instances the bullet passed through the abdominal cavity at or above the level of the umbilicus in an antero-posterior direction, passing through the body. In one of the military hospitals I saw a patient fully convalescent from a gunshot injury which implicated the cavity of the chest and liver. Bile escaped through the anterior opening for a number of days; no operation; rapid recovery under expectant treatment. Cases of erysipelas were few and mild. In gunshot fractures of the extremeties progressive phlegmonous inflammation occasionally set in, necessitating extensive drainage or amputation. The Surgeon-General's office had no record of any cases of pyemia. Death caused by infection resulted from progressive sepsis. Field and hospital practice did not show a single case of hospital gangrene. Many of the large lead bullets obtained by extraction or amputation were greatly depressed. I will now give a brief account of some of the cases of gunshot injuries which I had an opportunity to examine in the different military hospitals for the purpose of showing what modern surgery has done in the way of saving life and lessening suffering of those engaged in warfare, thus greatly mitigating the remote horrors of the battlefield. Antiseptic surgery can not claim all the good results which followed the treatment of the wounded during the last war, as after the battle of Bordino in 1812, long before antiseptic surgery was known and practiced, comparatively few cases became infected. The good results in part at least are due to the favorable climatic influences and the excellent constitutional condition of the injured.

Marseilles Hospital.—This one of the temporary military hospitals has received its name in honor of a wealthy lady of Marseilles who endowed it so liberally for the present purpose. It is the Polytechnic school, and as soon as all the patients are disposed of will again become an educational institution. The nursing in this hospital has been done principally by a number of Danish sisters from Copenhagen, whose services have proved most acceptable to the authorities and patients. Of 100 patients admitted into this hospital suffering from gunshot wounds, only one died. At present about fifteen wounded soldiers remain, all of them on the way to recovery. The medical cases are made up of malaria and two typhoid fever patients.

Tratiotikon nosocomion.—This is the regular military hospital, erected and used for the exclusive use of sick and wounded soldiers. It is sixty years old and has a capacity of 500 beds. It is built on the barrack system and is well lighted and ventilated. It is asserted that in this hospital three patients recovered without laparotomy who were admitted with perforating gunshot wound of the adbomen. The fatal cases of this kind of injury probably never reached their ultimate destination. There can be but little doubt that a number of cases of perforating gunshot wound of the abdomen recovered without operative intervention, which only goes to prove what the writer demonstrated years ago experimentally that not all perforating gunshot wounds of the abdominal cavity are complicated by visceral injuries of sufficient severity to require abdominal section, or to become the immediate cause of death. The nursing in this hospital is done by soldiers and a few English nurses. The operating room is small, but is supplied with all the essential equipments and materials for aseptic work. All of the operations are performed by the regular military surgeons.



MILITARY HOSPITAL AT ATHENS.

Case 1.—Gunshot wound of the head. The bullet entered above the orbit and passed out of the skull in the parietal region on the same side. No operative treatment. Healing of the wounds of entrance and exit by primary intention. No focal symptoms at any time. Patient fully convalescent.

Case 2.—Gunshot wound of forearm. No fracture of the bones. A German surgeon attempted to find and extract the bullet with negative result. A long scar marks the line of incision. Slight suppuration. Wound now nearly healed. Patient walking about with the forearm supported in a sling.

Case 3.—Bullet wound at the base of right thigh; wound of entrance near the border of the sartorius muscle, wound of exit near gluteal crease. Healing by primary intention.

Case 4.—Wound of right knee joint, received in Epirus. The bullet fractured the internal condyle of the femur, opened the knee joint and was removed by an incision over the outer aspect of the joint. Aseptic healing of the wound with fair degree of motion of the joint. Considerable thickening of the capsule of the joint remains.

Case 5.—Gunshot fracture of leg, with extensive comminution of fibula. Wound received during the first week of the war. Healing by secondary intention and slow formation of callus.

Case 6.—Bullet wound of base of neck. The bullet passed transversely through the soft tissues of the neck, behind the vertebral column and probably caused a fracture of one or more of the spinous processes. The special symptoms due to concussion which followed the injury have now disappeared and were probably caused by concussion of the cord. Healing of the wound without suppuration.

Case 7.—Bullet wounds of chest. Three wounds of entrance over the anterior and upper aspect of the chest. One of the bullets passed through the chest on the left side of the sternum, point of exit over the scapula on the same side. The other two wounds were inflicted by the contents of a bursting shell. The size of the scars indicate that the missiles were less than 38 caliber in size. No attempt was made to locate and remove these bullets. Free hemoptysis immediately after the injury. The patient recovered without any grave complications setting in.

Case 8.—Comminuted gunshot fracture of tibia. Many fragments of bone were removed soon after the injury was received, leaving a large bone defect. Wound healed; no union and but slight callus production. An operation for pseudo-arthrosis will become necessary in the near future.

Case 9.—Gunshot wound of chest with fracture of spinous processes of one or more dorsal vertebræ. Track made by bullet transverse, about the junction of the middle with the upper third of the dorsal portion of the spine. Pleural cavity not opened. Wound of entrance on one side of the spine, incision made for the extraction of the bullet on the other side on the same level. Spinal symptoms were well marked immediately after the injury was received and are disappearing rapidly. Wound healed without suppuration.

Case 10.—Gunshot wound of knee joint with extensive comminution of internal tuberosity of tibia. Patient a captain in the Greek army. First dressing applied fifteen hours after the injury was received, redressed on the sixth day. Bullet passed through the joint and escaped between the head of the fibula and the external condyle of the femur. Injury inflicted during the beginning of the war. Slight suppuration. Wound now healed; capsule of joint and para-articular tissues remain somewhat swollen and indurated. Considerable impairment of motion. No operative treatment.

Case 11.—Gunshot injury of leg. Patient a lieutenant in the Greek army. Bullet passed from before backward through the leg a few inches below the knee joint, between the tibia and fibula, without fracturing either of the bones. Primary healing of the wound without much functional impairment.

Case 12.—Gunshot wound of the shoulder joint. Wound of entrance two inches below the acromion process. The bullet passed through the head of the humerus and the shoulder joint and was removed in the field hospital at a point two inches below the middle of the clavicle. Conservative treatment. Healing of wound without suppuration. No anchylosis and no swelling of joint. Humerus at the seat of injury considerably enlarged by callus formation. Patient is able to raise arm at a right angle to the body.

Hospital Evangelismos.—This is the best hospital in Athens and furnishes accommodation for 150 patients. The surgical wards are in charge of Professor Galvani, who performs on an average 350 capital operations annually. During the war and at the present time this institution has been used largely in receiving and caring for sick and wounded soldiers. The care of the sick is in the hands of native female nurses. These nurses are devoted workers but lack a thorough training. My attention was called to a number of very interesting gunshot injuries involving different parts of the body.

Case 13.—Gunshot wound of knee joint. The bullet perforated the external condyle of the femur and passed out over the minor aspect of the joint. Course of active treatment. Moderate swelling of joint; no suppuration. The wound healed by primary intention. Recovery with fair action of joint.

Case 14.—Injury of ankle joint produced by the bursting of a shell. Slight infection, healing of the wound by granulation. Joint remains considerably swollen and somewhat tender to pressure. Motion of joint limited.

Case 15.—Bullet wound of soft tissues of the leg. Healing by primary intention.

Case 16.—Similar wound. Healing without suppuration. In both instances the bullet passed through the limb without producing any injury to the bones.

Case 17.—Cretan, gunshot wound of shoulder joint. Bullet passed through head of humerus and joint, point of exit below coracoid process. Fistulous opening remains, through which a limited amount of pus passes daily. Anchylosis not complete. Considerable atrophy of deltoid muscle which may be due to nerve injury.

Case 18.—Gunshot wound of chest. Bullet not extracted; injury followed by empyema. Free drainage without rib resection. Injured side of chest contracted; respiratory movements greatly diminished. Patient is pale and emaciated and shows the effects of prolonged suppuration.

Case 19.—Gunshot fracture of thigh. Injury received four months ago. Wound healed; bone united by massive callus; limb considerably shortened and femur curved.

Case 20.—Gunshot wound of chest and abdomen. Bullet entered dorsal side of chest on level with eighth rib four inches from median line, took a downward and forward course and escaped below costal arch an inch below cartilage of seventh rib. No operation. Bile escaped through anterior perforation for a number of days. Wound healed by primary intention. No serious inflammatory complications. Patient is now fully convalescent.

Case 21.—Gunshot wound of ankle joint. Moderate suppurative synovitis followed the injury. Wound of entrance granulating. Joint considerably swollen; heel retracted; motion greatly impaired.

Case 22.—Gunshot wound of patella opening knee joint. Secondary suturing of patellar fragments with satisfactory result. Motion of knee joint greatly impaired, which in part is due to the swelling and induration of the soft structures which still remain. Suturing material, silkworm gut; operator, Professor Galvani.

Dase 23.—Gunshot wound of heel. Extraction of bullet in the field hospital. Suppurative; suppurating fistula leading down to denuded os calcis remains.

Case 24.—Perforating gunshot wound of the abdomen. Recovery without operation.

Case 25.—Gunshot wound of abdomen. Recovery without operation. Cases previously mentioned. Both of these cases entered the hospital ten days after the injury was received.

Case 26.—Gunshot fracture of both bones of the forearm. Bullet and loose fragments of bone removed in the field hospital. No union and no callus formation. Wound healed.

Case 27.—Gunshot fracture of the humerus. Bullet passed through the arm near the middle. Nerves escaped injury. Healing by primary intention. No splints. Fixation by bandaging arm to the side of the chest with forearm fixed and supported by the same bandage. Union by bony callus with good functional result.

Military academy transformed into temporary hospital.—This institution could readily accommodate 300 to 400 patients. It is well adapted for hospital use. Twelve English nurses were employed during the war in caring for the sick and wounded, assisted by soldiers. At present only one nurse remains and the number of patients has been reduced to less than two hundred.

Case 28.—Gunshot wound of thigh. Infection. Secondary amputation. Osteomyelitis of the bone made it necessary to perform a second operation, which consisted in enucleating the bone. Wound still suppurating and healing slowly by granulation.

Case 29.—Gunshot wound of clavicle and scapula. Clavicle united by a massive callus. Bullet passed from before backward, above the large vessels and nerves. Motion of arm greatly impaired.

Hypaxiomatikon Hospital.—This is another temporary military hospital. It is an old military school which was converted into a hospital soon after the breaking out of the war. More than five hundred patients have been treated here. It gives accommodation for 110 patients and is fairly well equipped for the present purpose. It is now used for convalescents almost exclusively. Of the present 110 patients 50 are recovering from injuries received during the war.

Camp and hospital diseases.—The prevailing disease among the soldiers in the field and in the hospitals is malaria. The average soldier is perfectly familiar with the use of quinin, which is the only drug used in the treatment of this affection. Typhoid fever and pneumonia have claimed a number of victims. As a rule typhoid fever pursues a comparatively mild course and is not treated by any of the aggressive methods. Complications are watched for and promptly treated when they appear.

Athens, July 28, 1897.

Rectoscopy.—Finding that metal tubes 15 to 40 cm. in length could be safely introduced into the rectum, S. v. Federoff has invented a rectoscope on the principles of the esophagoscope, but separate from the light, 2 to 2.5 cm. in diameter, with a rubber obturator, the patient in the lithotomy or knee-elbow position. Inserted gently, it can be worked up into the flexura sigmoidea as far as the mesosigmoideum will allow, which varies in different persons. Photographs of the rectum can be taken through this rectoscope, and carcinoma can be differentiated with it alone, while it is also valuable for other obvious purposes.—*Cbl. f. Chir.*, July 31, from *Chirurguija*, 5.

THE "SCHOTT TREATMENT" OF CARDIAC DISEASE.

Read in the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY C. N. B. CAMAC, M.D.
FIRST ASSISTANT RESIDENT PHYSICIAN JOHNS HOPKINS HOSPITAL, BALTIMORE, MD.

The "Schott treatment" for chronic heart disease, although well established in Germany and England, is so little known in America that it warrants a word of explanation before going on to the description of the cases treated by this method at the Johns Hopkins Hospital.

Nauheim first came to the notice of Europeans in 1834. It was not until 1860 that Dr. Beneke of Marburg considered scientifically the value of the medicated bath treatment. From 1859 to 1870 his articles on the waters of Nauheim made their appearance in the *Berliner klinische Wochenschrift;* from 1870 to 1890 August and Theodore Schott and J. Groedel were frequent contributors on this subject to this journal. August Schott died, but his brother continued the work and published one of the first articles to appear in English print in 1892. Although this article appeared in the *Lancet* it received but little attention, and it was not until 1894 that, upon the publication of an article by W. Bezley Thorne, in the *Lancet*, the treatment came to be discussed in medical circles. Shortly after the appearance of this article, the same author published a systematic explanation of the treatment and how it could be artificially employed. Since the appearance of this book the literature in England and Germany has been crowded with articles on the subject, as may be seen by the extensive bibliography.

Nauheim is situated in the Grand Duchy of Hesse, three-quarters of an hour's ride by train from Frankfurt and two hours' from Homburg, at the eastern slope of the Johannesburg, the last spur of the Taunus mountains. The springs are divided into two classes: those suitable for drinking and those for bathing. The principal ingredients of the waters are sodium chlorid and calcium chlorid, various salts of iron, and an abundance of carbonic acid. Their natural temperature ranges between 82 and 95 degrees F. Spring No. 12 rises some fifty to fifty-six feet above the surface, forming a most beautiful fountain, the waters with their rich supply of carbonic acid gas falling into a seething mass in the basin below.

These waters are led to various houses in which are the bath rooms. Although the waters vary naturally in strength, they are, nevertheless, altered artificially to suit the requirements of the bather. About the central spring are situated these numerous bath houses with their varying strengths indicated by the numbers 1, 2, 3, 4, 5 and 6. A patient is ordered by his physician to take such a one of these as may be deemed advisable. Learning, therefore, the constituents of these waters and the conditions to which each is applicable, it becomes a mere matter of careful analysis and proper instruction to administer these baths artificially. Fresenius the State chemist at Wiesbaden has given a careful analysis, by following which the artificial baths may be prepared. The baths at the Johns Hopkins Hospital have been conducted upon the basis of these analyses.

It is of interest to inquire first in what way these baths act. That they have been efficacious in the relief of chronic heart disease was made evident before the subject was taken up by the brothers Schott. That there is a diminution in the area of cardiac dulness, that there is a change in the position of the apex beat, was also made evident. There was, therefore, under this treatment some distinct change in the degree of congestion of the internal organs and a gradual reduction of a dilated heart. That there was relief from the dyspnea and distress so commonly associated with chronic heart disease, being established on the one hand; that there was a relief of the congestion of the internal organs, evidenced by the reduction of the area of cardiac dulness and an increase in the amount of urine secreted and a diminution of pleural effusions established on the other hand, the question as to how these changes were brought about came to be actively discussed. Throughout the range of literature on this subject, no satisfactory explanation has as yet been given. While Dr. Schott's view, that the salts held in solution pass by imbibition through the outermost layers of the epidermis and so act upon the terminal nerves of the skin, exerting a reflex action on the internal organs, sounds perhaps satisfactory, yet one looks for an explanation which is less of the nature of an hypothesis. In support of his view he mentions that excessive bathing induces an excitable state of the nervous system, sleeplessness and loss of appetite, but this can hardly be considered as proof that the action of the Nauheim waters on the terminal nerves, is accountable for all the changes which result in the internal organs. Nevertheless the conclusion that all these extensive changes are in reality the result of a reflex action produced by influences upon the terminal nerves it must be admitted, is plausible. Thorne's statement, that there is a dilatation of the muscular arteries, and afterward of those of the skin, thus relieving the congestion of the internal organs, is but a part of the explanation and although he adds another link to the chain he by no means completes the explanation. How is this dilatation brought about? True, Dr. Schott states that the calcium chlorid is the active stimulant to the terminal nerves through imbibition. Dr. Lauder Brunton, in his massage experiments, demonstrates that more blood flows through the massaged part, and that blood pressure first rises and then falls, but that on the conclusion of massage more blood collects in the massaged parts; experiments which were confirmed by Dr. Oliver.

Ludwig has shown that the capacity of the muscles for blood, is equal to the combined capacities of the internal organs and the skin. In these two experiments, we think we find the most satisfactory explanation of the action of both the baths and the exercises; for, if Dr. Lauder Brunton's experiments in massage be correct, and the conclusion of Ludwig be correct, the increased amount of blood in the muscles must indicate a relief of congestion in the internal organs. That there is more blood in the part and necessarily a dilatation of the muscle arteries is proven by increased displacement of the limb. We are yet at a loss to find the link between the action of the salts upon the skin and the increase in the amount of blood in the muscles. If, however, we accept Dr. Schott's explanation of the cutaneous excitation by the gaseous and mineral constituents, followed by a more prolonged stimulation of the sensory nerves produced by a the imbibition of the salts into the superficial layers of the corium, we perhaps, have this missing link in the chain of explanation. To sum up the various theories which have been advanced, the calcium chlorid of the salt-waters is imbibed into the superficial layer of the corium producing a superficial cutaneous excitation first and then a stimulation of the deeper sensory nerves, these in turn leading to a dilatation of the peripheral vessels with a consequent increase of blood in the muscles and the skin, *whose combined capacity far exceeds that of the internal organs*, the result being a relief of the congestion of the latter.

Having thus first reviewed the theories in explanation of the way in which these saline waters and the exercises act, the practical questions as to the treatment present themselves. I shall confine myself solely to the administration of the exercises and artificial baths. The course of baths consists of six different strengths; the first and second consisting of different proportions of calcium chlorid and sodium chlorid; the third, fourth, fifth and sixth contain carbonic acid as well as these salts. By the expression "course" of six baths is not to be understood that every patient is submitted to the whole six strengths. It simply means that according as the patient improves the bath is increased in strength; for example bath No. 1, may be administered for a period of several days, the patient failing to respond to it; No. 2, is given and if there be still no response No. 3, and so on even to the full strength, that is bath No. 6. Frequently it is not necessary to go higher than the fourth bath either because the patient shows distinct improvement with the strength already employed or because there is all absence of improvement and his condition contraindicates further submitting him to the treatment.

Bath No. 1, consists of sodium chlorid 4 pounds; calcium chlorid 6 ounces.

Bath No. 2, sodium chlorid 5 pounds; calcium chlorid 8 ounces.

The following baths have together with these salts carbonic acid which is produced by the action of hydrochloric acid and sodium bicarbonate.

Bath No. 3, consists of sodium chlorid 6 pounds; calcium chlorid 10 ounces; bicarbonate soda 6 ounces; hydrochloric acid 7 ounces.

Bath No. 4, sodium chlorid 7 pounds; calcium chlorid 10 ounces; sodium bicarbonate 8 ounces; hydrochloric acid 12 ounces.

Bath No. 5, sodium chlorid 9 pounds; calcium chlorid 11 ounces; sodium bicarbonate 1 pound; hydrochloric acid 1 pound.

Bath No. 6, sodium chlorid 2 pounds; calcium chlorid 12 ounces; sodium bicarbonate 1 pound; hydrochlorid acid 2 pounds.

These various amounts of salt we have put up in packages and labeled bath No. 1, 2, 3, etc., and any strength of bath can be made up by ordering these packages. The calcium chlorid is best prepared in solution. The above proportions correspond to 40 gallons of water, which is just about enough to entirely immerse the body. The bath is given in the morning unless otherwise deemed advisable.

The following are the rules which have been laid down for the administration of the bath. Most of these rules have been made after perusal of the literature and from instructions obtained from Dr. Schott personally.

The bath should be given on an empty stomach; allow the patient to make as little exertion as possible; assist him in every way. A sheet may be drawn over the tub but not around the patient. Be sure that the entire body is immersed. Keep the finger on the pulse during the entire time the patient is in the bath.

Danger signals.—Cyanosis; dyspnea; apnea; inappreciable pulse. On the appearance of any of these, take the patient out of the bath immediately, put him to bed and keep him as quiet as possible. Friction while in the bath is not necessary, but if the fingers and toes become bluish the extremities may be rubbed slightly toward the trunk. Friction should be cautiously employed; when the patient is out of the tub rub him to a glow; give him a glass of milk or cup of bouillon and allow him to rest for an hour.

Diet.—Small quantity q. 4h. meat, boiled chicken, mutton chops; eggs, two a day; oysters raw or panned; vegetables of all kinds; peas, beans, lettuce; liquids; beef tea, bouillon, cocoa, lemonade, milk. *Note.*—Never give more than 4 ounces of fluid at a time: Should be sipped. *Wine.*—Port, Rhine, sherry; brandy; dram to half ounce.

Note.—Something light (cocoa and toast) should be taken one hour before the bath; something light and hot (bouillon, milk punch and toasted crackers) should be taken directly after the bath. If the heart's action is poor, sherry, brandy or port wine may be given after the bath. Last meal to be taken three hours before retiring.

The exercises which are called by Dr. Schott "Widerstandgymnastik" or resistance gymnastics are slow movements executed by the patients and resisted by the physician or operator. The exertion is the very least that can be employed and should cause no fatigue on the part of the patient. Light, loose clothing should be worn by the patient and he should be instructed to breathe quietly. It is hardly necessary to give full explanation of the exercises here as it demands considerable attention and is more in the order of a drill than of an explanation. It is important however to state that these movements should not be administered without thorough training from one competent to give it. The movements are nineteen in number and involve all the larger muscles of the body. This portion of the treatment we have entrusted to our nurses, who have received thorough instruction and whom we find are better adapted to the administration of, the light resistance than are men.

Since November we have had under treatment ten cases. Of these ten we have had four deaths, two have shown no improvement, one has shown improvement only during the treatment and three have shown continued improvement.

No one would claim to cure cases of chronic heart disease; all that one can hope for is to place the heart in a functional condition which in relation to the rest of the organism is the best possible compatible with the lesion which exists. In the three cases which have shown continued improvement the results have been very satisfactory, one might say even striking. Of the four deaths No. 1 was a case of aortic insufficiency; No. 2 of dilatation and arterio-sclerosis; No. 3 of chronic nephritis; No. 4 of mitral stenosis. Although the chronic nephritis case was manifestly inappropriate to the treatment, it was selected for the purpose of noting the action upon the kidneys.

In this case, a young girl whose condition at no time was hopeful, the edema of the genitalia and lower extremitities on admission being so extensive that it was impossible to approximate the legs. The features were almost unrecognizable. Beyond a very slight response amounting to about 500 c.c., there was no increase in the urine excreted. As an extreme case, therefore, of chronic nephritis this was in no way aided by the treatment. Another case, on the contrary, of chronic interstitial nephritis and tachycardia, the action upon the excretion of urine was most striking. The patient was removed to the isolation ward owing to the unmanageable condition in which she was, following uremia.

The following is a synopsis of the urine record. Record begun December 9.

1. Between December 9 and January 20, *forty-three days.* Urine fell below 900 c.c., in twenty-four hours, *twenty-one times.*

Treatment.—Nitroglycerin, continued throughout period of forty-three days; patassium iodid, tr. digitalis, sol. diuretin, sweat baths, cream tartar water, citrate of lithia, apollinaris.

Condition of patient.—Delirious, requiring forcible restraint.

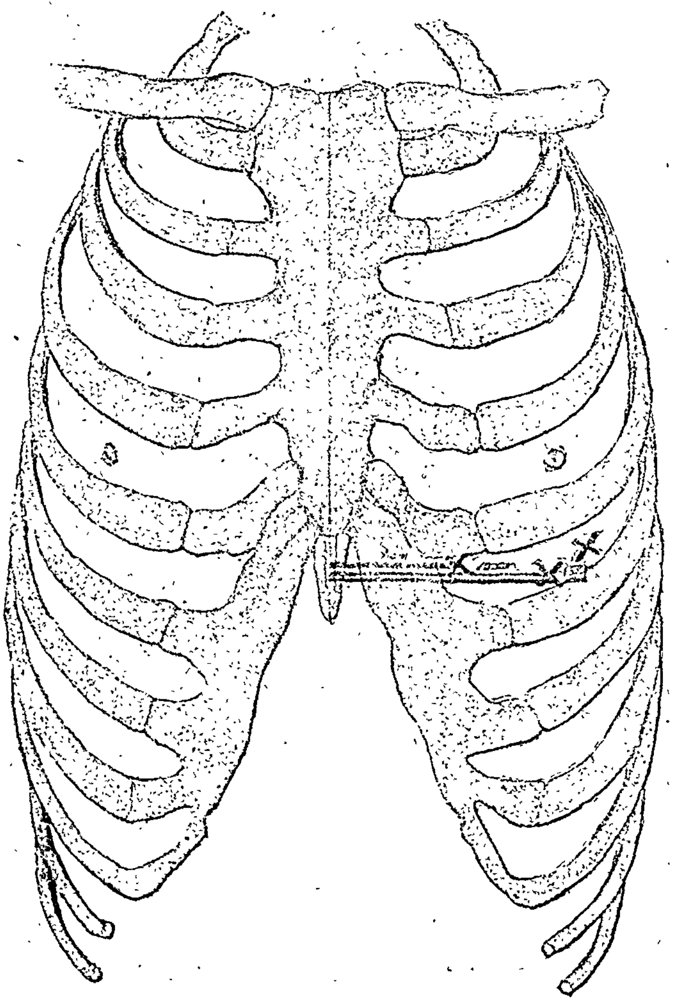


Chart No. 1.—Hunt. Feb. 12. Before bath No. 1, strength No. 1. Point max. imp., 5th space, 13½ cm. from median line; after bath, point max. imp., 5th space, 11 cm. from median line. Feb. 13, no bath given. Point max. imp., 5th space, 10 cm. from median line. Feb. 14, bath No. 2, strength No. 1. Point max. imp. after bath 5th space, 8 cm. from median line. Feb. 15, no bath given. Point max. imp. not located. No signs (physical or post-mortem) of effusion.

2. Between January 20 and March 2, *forty-two* days. Urine fell below 900 c.c., in twenty-four hours, *four times.*

☐ *Treatment.*—Nitroglycerin, apollinaris, Schott baths, hot baths, continued throughout period of forty-two days; tr. strophanthus, tr. digitalis, strychnia, potassium iodid.

Condition of patient.—Rational; does not sleep well.

3. Between March 2 and 11, *eight days.* Baths were discontinued. Urine fell below 900 c.c., in twenty-four hours, *six times.*

Treatment.—Tr. digitalis, citrate potash, nitroglycerin, apollinaris, sweat bath, pilocarpin.

Condition of patient.—Dyspnea; 280 c.c. urine on March 6; 210 c.c. urine March 9; small irregular pulse.

4. Between March 11 and April 7, *twenty-eight days.* Resisted movements and baths. Urine fell below 900 c.c., in twenty-four hours, *five times,* upon each occasion with an interval of at least three days.

Treatment.—Nitroglycerin, apollinaris, strychnin, Inf. digit.. Schott bath No. 3, resisted movements Nos. 1, 2, 4, 5, 6, 9 and 10.

Condition of patient.—Out on grounds; sleeps well; no dyspnea. Discharged April 7.

This case we considered as receiving benefit only during treatment. The improvement was not lasting.

The second fatal case (the first being the chronic nephritis in the girl first mentioned) was that of a colored man with marked signs of aortic insufficiency, accompanied by the Flint murmur at the apex. This was an extreme case whose condition had become so serious that he was removed to the isolation ward. So far from the median line was the apex beat that it seemed a suitable case upon which to note the effect of the baths. The point of maximum impulse was seen in the fifth space, 13½ cm. from the median line. After the first bath the apex beat was seen in the fifth space 11 cm. from the median line. The day following, the maximum impulse was seen in the fifth space 10 cm. from the median line and on the following day a second bath was given and the apex beat was found in the fifth space 8 cm. from the median line. The patient improved very markedly, became clearer in his head, and was qui[illegible] manageab[illegible] On the 16th, four days after the [illegible] p[illegible] suddenly. An effusion at [illegible]sts [illegible] there were no signs of [illegible]

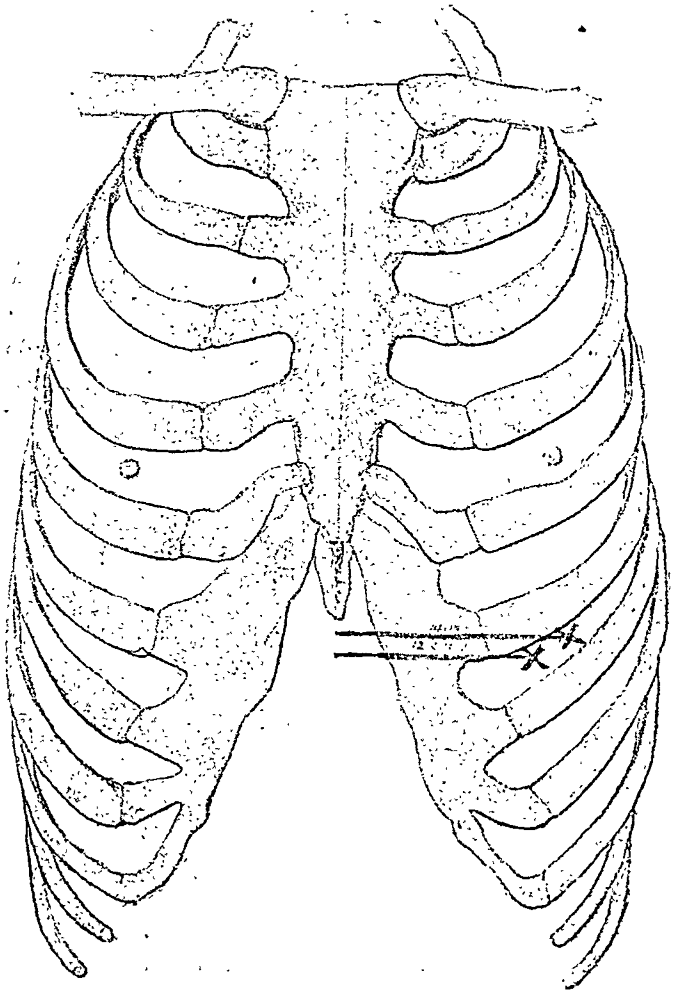

Chart No. 2.—Larber. Before bath No. 1, strength No. 1, point max. imp. 14 cm. from median line. After bath, point max. imp., 12 cm. from median line. Length of time in bath, five minutes.

Charts Nos. 1 and 2 illustrate the *immediate* influence of the baths upon the point max. imp.

The third fatal case was a private one who showed signs of cardiac dilatation and a moderate degree of thickening of the vessels. This patient was given movements from February 21 to April 4. He was extensively edematous, especially the legs. It was never possible to make very careful examinations of the cardiac outline. The pulse, however, which had been very weak and of small volume, improved very distinctly in the course of the treatment. The edema almost wholly disappeared and the patient from being confined to a chair was able to be up and occasionally to drive. March 29 and 30, he took a drive and slept well. On March 31 he had a very restless night but on April 1 was again able to drive. For this patient this was a very great improvement considering he had spent months in his room. On April 3 he had a very restless night and from this date he steadily declined, dying suddenly on April 7.

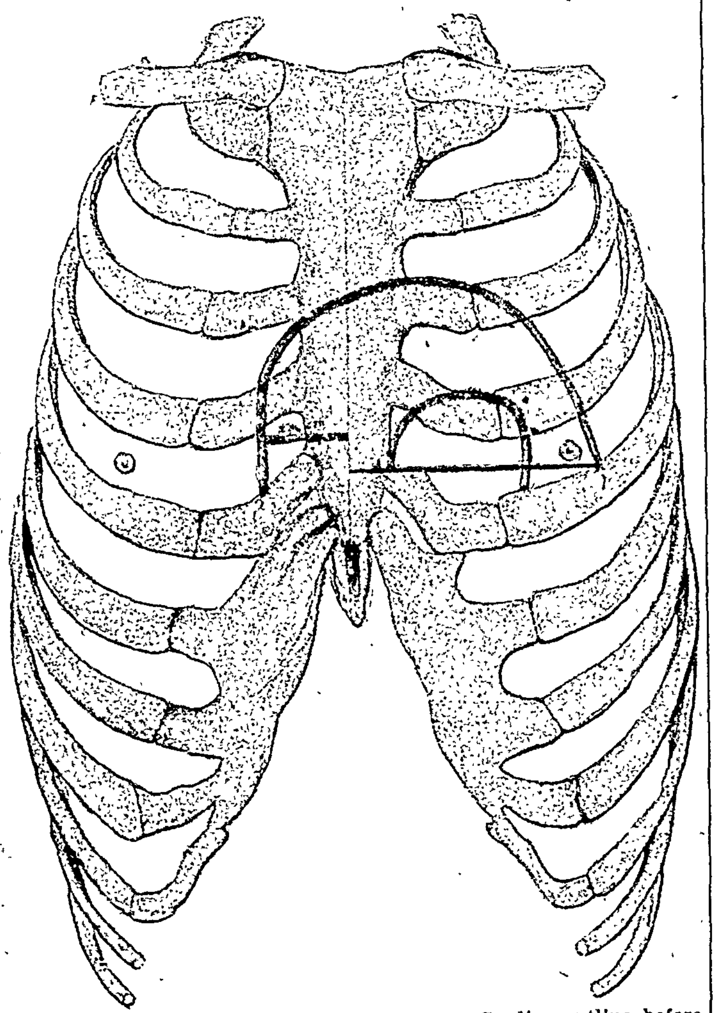

CHART No. 3.—Coulbourn. Oct. 13, 1896. Cardiac outline before bath No. 1, strength No. 1. Right border 2¾ cm. from median line. In bath eight minutes.

The fourth fatal case was one of mitral stenosis. The change in the apex beat was very striking. This man came into the hospital suffering from great dyspnea and distress and cyanosis; under the treatment he was able to be up and about the ward, and on the day before Christmas was so much improved as to go to his home. He was, however, an intemperate fellow and got into a spree on Christmas Eve, during which he fell dead. (Chart No. 2.)

In these four fatal cases are shown the marked influence upon, 1, the position of the apex beat; 2, the increase in the amount of urine in spite of the nephritis in one case; 3, the very marked improvement in the pulse in the case of the cardiac dilatation which was associated also with arterio-sclerosis; 4, the inefficiency of the treatment on a case of extreme nephritis.

The two cases which showed no improvement, one was that of cardiac dilatation, and glycosuria; the other cardiac dilatation with chronic nephritis. Although the area of cardiac dulness was diminished and the pulse tracing, which were taken by Dr. McCrae, assumed a more definite character, the edema never diminished and the patient was discharged practically unimproved (charts 3, 4, 5). We therefore see that in these seven cases so far reported, those in which the kidneys were extensively involved, no improvement resulted. In those cases in which there was nephritis but of a less severe grade the improvement could scarcely be regarded as such, so transient was it.

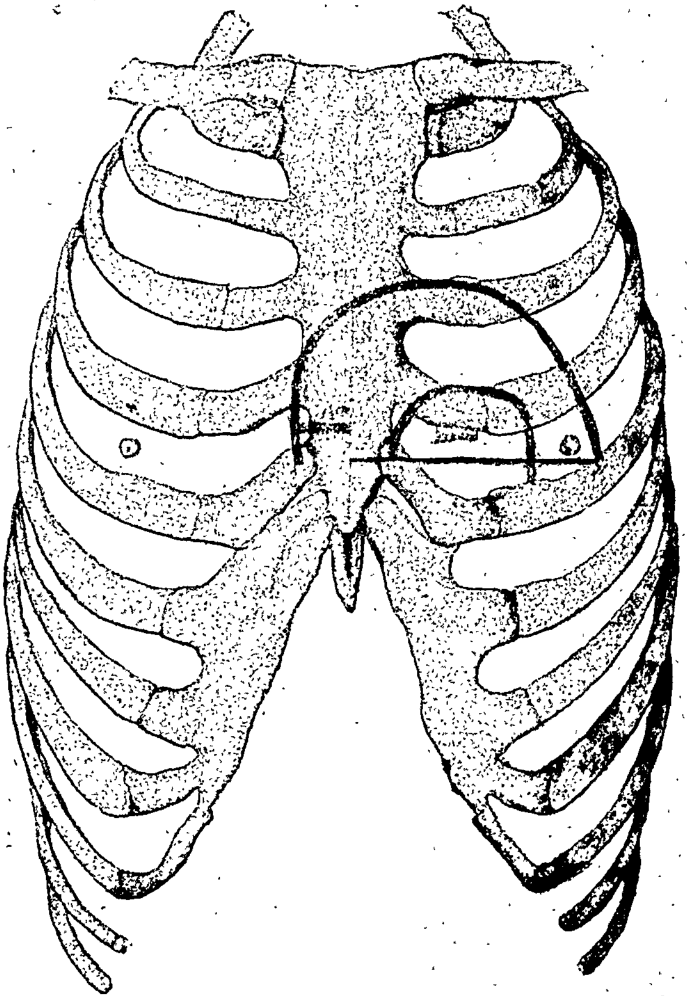

CHART No. 4.—Coulbourn. Oct. 18, 1896. Cardiac outline after bath No. 6, strength No. 1. Right border 1½ cm. from median line. In bath eight minutes.

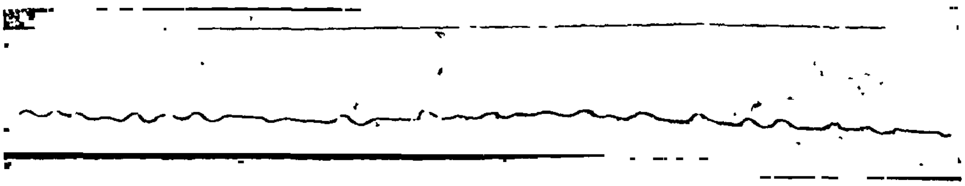
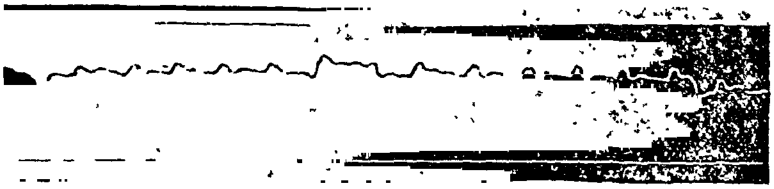
NOTE.—In Charts 3 and 4 the outline on the right side of the chest extends too far laterally. It did not extend beyond the nipple. There was no change in his line after treatment.

Charts Nos. 3 and 4 illustrate change of 1¾ cm. in cardiac area after six baths of strength No. 1.

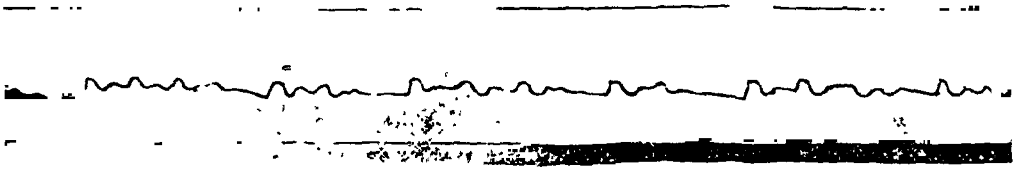
Of the three cases of continued improvement, the most striking is that of a colored man. It is a fact to be noted that whereas the white patients will resist for a long time vascular changes, yet in the colored race the outlook is relatively much graver. This was an old case who had visited the hospital a number of times and upon his last admission it was noted that there was a distinct thickening of the vessels. He improved very markedly under the treatment and although the baths were stopped at a date long before he was discharged from the hospital, he nevertheless,



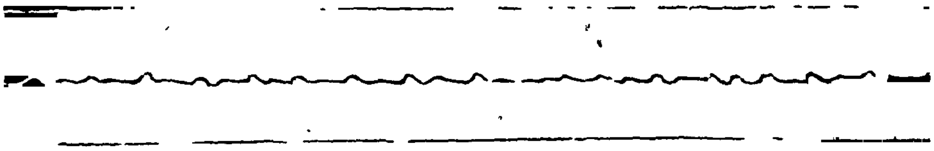
1. October 13, before treatment, 4¾ hours before first bath.



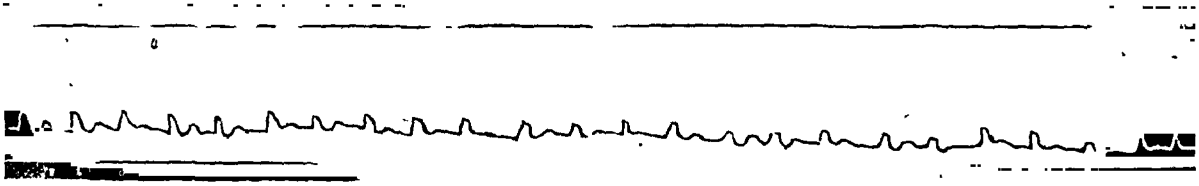
2. October 13. Bath No. 1, strength No. 1, at 4:30 P.M.



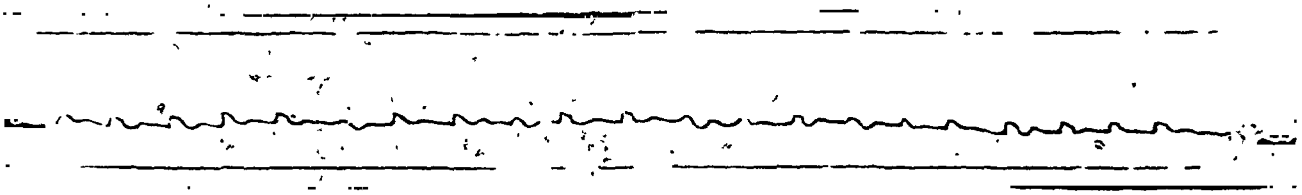
3. October 13, 10 P.M., 5½ hours after first bath.



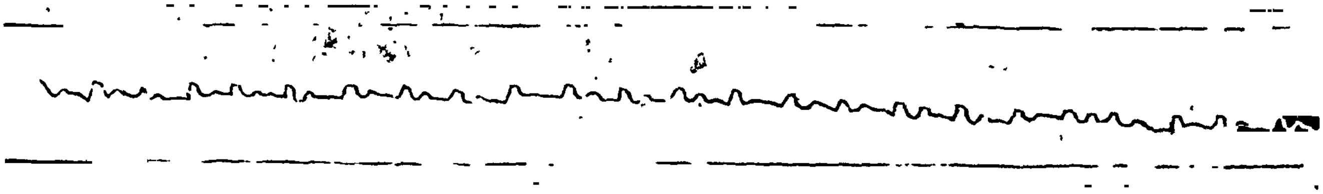
4. October 15, after third bath, strength No. 1.



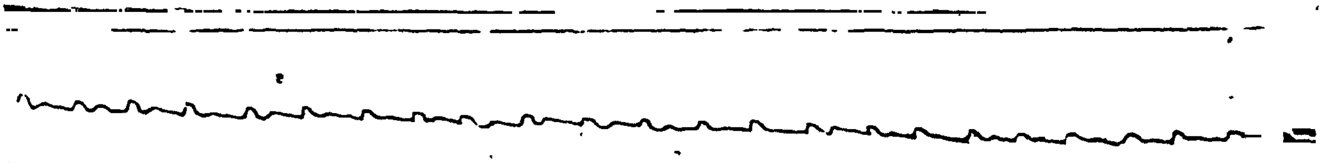
5. October 18, after sixth bath, strength No. 1.



6 October 22, after eighth bath strength No. 2.



7. October 26, no bath given on 24th or 26th.



8. October 30. No baths given since 27th.

CHART No. 5.—Coulbourn. Series of tracings to illustrate the regulating effect of the baths upon [illegible] dysp[illegible], was so severe that baths had to be discontinued.

Schott Method of Baths and Resisted Movements.

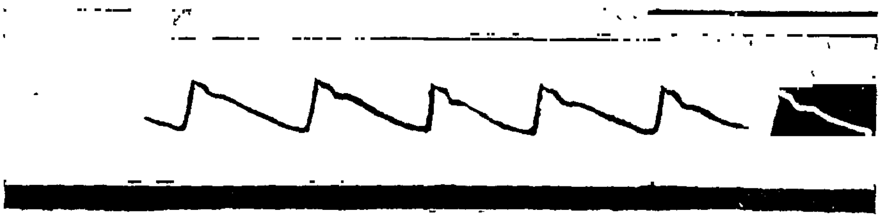
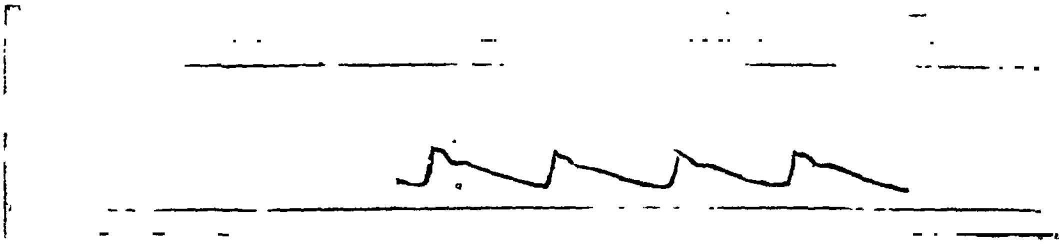
CHART No. 6—Showing method of recording observations. For pulse tracing of this case see Chart No. 7.

while under observation was most comfortable, having no return of his dyspnea or edema. In this case the point of maximum impulse instead of being moved in was moved out. (Chart No. 6.)

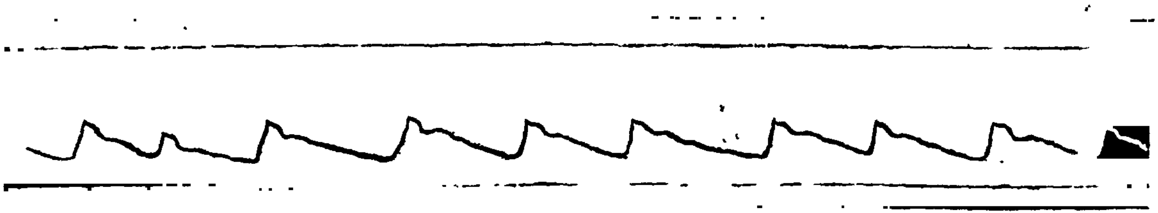
An interesting comparison may be made between this case and that of Hauser (Chart No. 8), to be mentioned immediately, with especial reference to the action of digitalis upon the pulse, and that of the baths. Chart No. 8 shows the influence of large doses of tr. digitalis given for a limited time at short intervals.



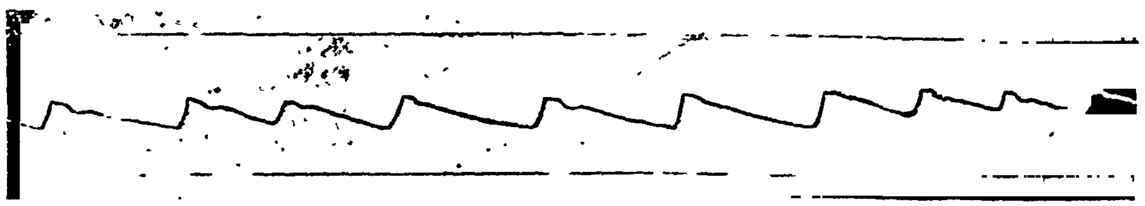
1. Williams (colored). Before bath No. 1, strength No. 1, Feb. 27, 1897.



2. After bath.



3. March 1. Before bath No. 5, strength No. 2.

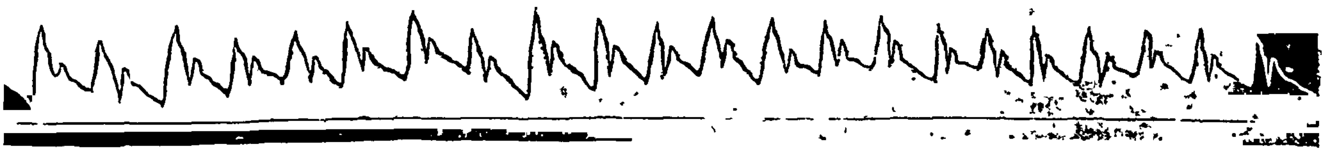


4. Immediately after bath.

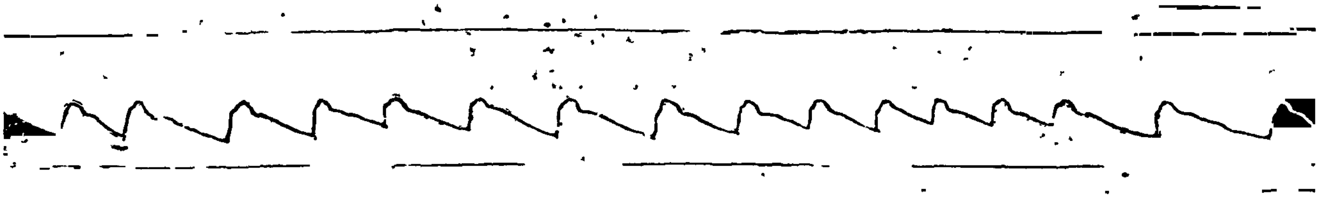
CHART No. 7—NOTE. By some mistake strengths Nos. 1, 2 and 3 were given in succession. Patient had received three baths before above tracings were taken; the character of the pulse was much improved in spite of this active treatment. Compare these tracings under bath treatment alone with Chart No. 8, tracings taken under tr. digitalis treatment alone.

Chart No. 7 (tracings taken by Dr. Reuling) shows the less striking but more lasting change under the bath treatment.

The second case was that of mitral insufficiency, who was given both the baths and movements. There was no change in the point of maximum impulse or area of cardiac dulness. The patient was discharged in good condition.



1. Before course of digitalis. Tr. digit. min. xv, q. 4 hours ad. ʒ ij.



2. After course of digitalis.

CHART No. 8.—Hauser. Period of one day and eight hours. Compare with Chart No. 7, where the period was three days under bath treatment alone. Slowing of pulse less marked with bath alone than with digitalis, but effects more lasting in former.

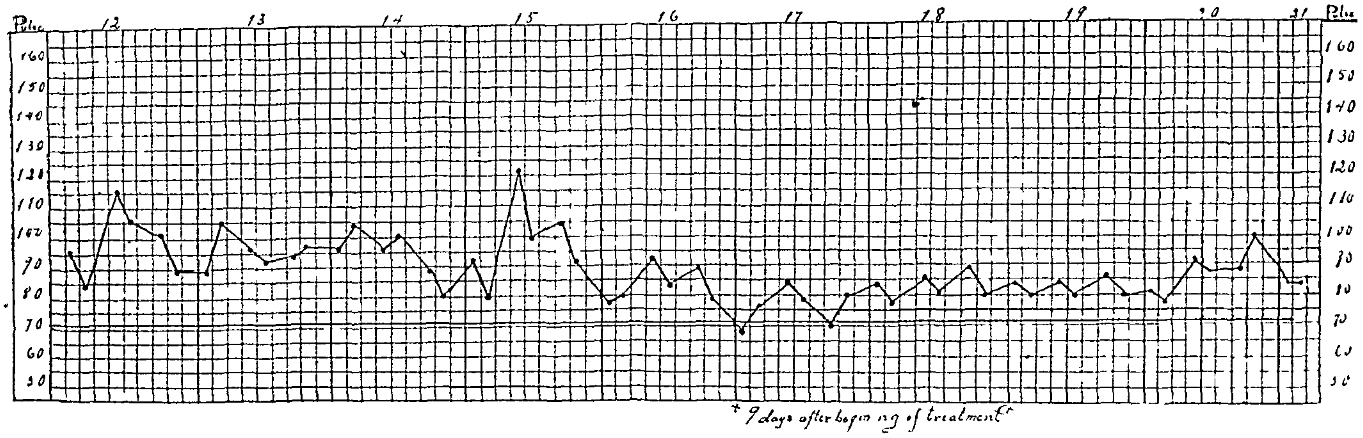


CHART No. 9.—Mrs L. (tachycardia.) Resisted movements, group 1, Nos. 1, 2, 4, 5, were administered daily, patient in recumbent posture. Chart showing steadying of pulse.

Name.	Diagnosis.	Treatment.	Condition During Treatment	Result.

2. Mr. C.	Cardiac Dilatation—Arterio sclerosis.	Baths and Exercises	Marked Improvement.	"
3. I. A.	Chronic Nephritis.	Baths only.	No Improvement.	"
4. G. L.	Mitral Stenosis.	Baths and Exercises.	Marked Improvement.	"
5. G. S . . .	Dilatation and Glycosuria.	" " "	No Improvement.	No Improvement.
6. B. C.	" " Chronic Nephritis.	" " "	" "	" "
7. Miss B. . . .	Tachycardia and " "	" " "	Marked Improvement only during treatment.	
8. W. W. (Colored)	Dilatation and Arterio sclerosis.	Baths only.	Marked Improvement.	Well.
9. J H	Mitral Insufficiency.	Baths and Exercises.	" "	"
10. Mrs. L . . .	Tachycardia.	Exercises only.	" "	"

The third case was one of tachycardia. The influence upon the pulse is seen in Chart No. 9. Of these three cases of continued improvement it will be noted that very little change took place in the point of maximum impulse, whereas in those cases which showed rapid improvement at first and which afterward terminated fatally, the change in apex was very striking. As far as our ten cases go the results are in favor of the following three points:

1. Extensive nephritis is a serious obstacle to good results from the baths and exercises, though if not too grave may be controlled by the treatment.

2. Extensive change in the position of the apex beat and cardiac outline do not necessarily indicate permanent good results.

3. Arterio-sclerosis may not wholly contraindicate the treatment.

In regard to the drugs employed, it may be mentioned that in the cases of nephritis, diluents were freely given. Infusion of digitalis was employed in dram doses every four hours and occasionally the tincture of digitalis was used. Potassium iodid was administered, although sodium iodid is considered preferable. Strychnia, morphia, tr. strophan., nitroglycerin, were also used in some of the cases.

The diet laid down in our rules, while not strictly adhered to, was in the main followed out. While we have found no consistent change in the point of maximum impulse or in the cardiac outline we have found in every case a slowing and strengthening of the pulse and a diminished tension. We regret that owing to the inability to procure a suitable arteriometer that the caliber of the radial was not properly recorded. It is our hope to pursue systematically the effect of the baths and exercises upon the kidneys. There seems to be here an important field for the treatment.

Naturally as yet our experience is very limited and this report is made simply to indicate the mode in which the measures are being tested at the Johns Hopkins Hospital.

DISCUSSION.

Dr. Wm. Osler of Baltimore—The introduction of the Schott method into this country is due, I think, to Dr. Babcock of Chicago, who demonstrated that it may be efficiently carried out in hospital practice and in private work. I have had cases treated at Nauheim with rather extraordinary results, and I have long known of the great enthusiasm displayed by Theodore Schott in his advocacy of this treatment. I think it will be, in a certain group of cases, a very positive advantage. The method of carrying it out is a little irksome and troublesome, but in any well-managed hospital, and indeed in private practice, it is perfectly feasible.

Dr. J. F. Jenkins of Michigan—I would ask Dr. Osler in what class of cases this treatment is indicated.

Dr. Osler—It is more particularly indicated in limiting the effect of cardiac dilatation without advanced nephritis and without much sclerosis of the arteries. Valvular disease itself is not a contra indication, and I think the most suitable group of cases are those of dilatation of the heart without much degeneration of the muscular substance, more particularly cases occurring in comparatively youthful subjects, or in men between 40 and 45 years of age who have persistently eaten much and taken too much beer.

Dr. Charles Stockton of Buffalo—I would call attention to the fact that by the Schott brothers great stress is placed on the manner of conducting these movements so that the patient may not be overtaxed and more harm than good be done. A second point to which I would call attention is the carbonic acid in the artificial bath. I feel satisfied that the mixture recommended by Thorn is not of much use, for the gas escapes as rapidly as it is produced, and has little effect on the skin. To overcome this difficulty, I have resorted to the use of an ordinary soda-water tank, and by conducting the escaping fluid under the water in the tub have been able to produce marked stimulation of the skin, and I feel convinced that this is a valuable addition to the saline constituents.

A third point relates to the mode of action of the bath upon the skin. I listened with much interest to what the reader said, and his explanation of this apparent stimulation of the capillary circulation, but I feel that there is still something [illegible]. The mere dilatation of the capillaries by heat, or by [illegible], or by any other means, does not necessarily increase heart [illegible]tion. Now, it seems to me there must be someting else in the action of this bath which adds certain force to the circulation. My friend Dr. Woods Hutchinson has an idea that there is communicated to the arteries a real propulsive force through the rhythmic contraction of the arterioles as a result of this stimulation.

Dr. Foster of Pennsylvania—I should like to know whether the author tried the ordinary bath in the treatment of any of these cases. He has related ten cases treated by the Schott method, and I should like to know whether he would have us infer that he regards that method with favor. Certainly the report of the cases would seem to be against it.

Dr. Herrick of Cleveland, Ohio—It seems to me that this subject has been treated within somewhat narrow lines; that an organ is being considered independently of the organism, and stress is placed on the importance of special treatment by special means, without consideration of the many circumstances leading up to the condition. We understand that the heart is subject to diseases in itself, and it is subject to disturbances of function by reflex relation to other organs. I am not quite satisfied with the etiology as stated. The treatment, it seems to me, has no reference to the etiology of the disease. Therefore I regard it with suspicion. The idea of the application of baths for an organic or functional disease involving the heart is somewhat beyond my comprehension. There is an antecedent condition which we should look after that involves the nutrition of that organ. That the reflex influence on the heart of the propulsive force of the arteries, etc., should produce any practical results I am not able to see. I am not familiar with this Schott treatment, so called. I wish to see the *rationale* between the therapeutics used and the disease. It seems to me that any treatment adopted should have a relationship to the etiology of the organic condition. I go back in my investigation of this subject to the question of nutrition—the nutrition of the heart. The heart may be disturbed by a variety of influences, mental or nervous or nutritional. I would say go back and look into the digestive organs. All nutrition depends upon certain factors, and all diseases involve disturbances of nutrition. We know that the heart is in more intimate sympathy with the digestive organs than with any others. Therefore, the first attention, and constant attention, should be given the digestive organs. In this it seems to me that we have a practical, a rational line of treatment, somewhat more definite than that of baths.

Dr. Smith of New York—The paper is pointed and practical. It is practical, inasmuch as the reader took into consideration the very facts referred to by the last speaker, those bearing on the relations of the general system to the disease of the heart. In the consideration of almost any disease we can not leave out the intimate relation existing between the different portions of the organism, and the sooner we fix in our minds the fact that it is the individual and not the disease that we have to treat, the better will be our results. There is a condition of sclerosis in which the general arterial system is involved in the first instance and a secondary effect is shown in the condition of the heart. I am very glad the first speaker (Dr. Osler) alluded to the effect of beer, or any kind of alcohol, but especially beer, in producing certain organic changes in the heart, what the Germans call the beer-heart. That is, it seems to have a transforming influence upon the capillary circulation, and that reacts upon the heart. Now, at the New York School of Clinical Medicine, I have used for the last six months the Ling system of physical exercise in the treatment of heart disease, and there is no question in my mind that that system when thoroughly carried out in appropriate cases has a marked influence in reducing the area of cardiac dulness. In the discussion which took place at the British Medical Association, by Thorn and Granger Stewart, due stress was laid upon the why and wherefore of the Schott exercises and due regard was given to the fact that it produced dilatation of the arteries throughout the muscular system, and consequently the propulsive power of the heart while not increased as to quantity was improved as to quality. That is, while the propulsive power of the heart was not increased in pulsation because it was slow, the heart muscle was toned up and intensified.

Dr. Jones of Buffalo—Schott has observed that the cardiac area has diminished and the pulse increased in volume from exercise alone and in a number of cases under baths. As I understand it, suitable cases after being treated there, are sent to the mountains, where the Örtel treatment may be carried out and after time come back to Nauheim and are treated again. The compensation does not last longer, perhaps, than it would under due rest in bed and digitalis.

Dr. W. B. Camac—In reading up the reports on this treatment it is very difficult to approach it without a biased mind. We decided to try the treatment and see absolutely what it would do, and the report of the ten cases have been presented from an unbiased standpoint. I think we have not been misled one way or another at Johns Hopkins, and in reply to the remark about being for or against the treatment, I may say that I believe we are neither one way or the other. We are still observing. I did not mean to slight the importance of the exercises, but they have been considered so frequently and in such detail that it did not seem necessary to weary you with the drill. This we have entrusted to the nurses. The importance of the very lightest resistance is made a great deal of, and one who is familiar with the treatment soon realizes how important it is to avoid all undue resistance which might lead to fatiguing of the patient. We have, therefore, trained nurses who administer the treatment under the supervision of a physician. The exercises are given as much attention to as the baths. We have found that carbonic acid gas can be satisfactorily formed according to the suggestion of Thorn, but not waiting five minutes, for in five minutes it has largely lost its power. Put the patient in almost immediately after the two ingredients are mixed, and the effect is accomplished in four or five minutes. If it is necessary to continue it, put in only one half of the mixture at first and the other half at the end of five minutes. The temperature of the bath is 82, 85 to 100 degrees F. The comparative effect of the ordinary hot bath and the Schott bath we have shown in the table. The baths were given in those instances alternately, the hot and the Schott. In most cases the amount of urine is greater after the Schott bath than after the hot bath. We must be governed by what we find. There is absolutely nothing to be learned from mere theorizing, and I trust the facts presented in the paper and the diagrams will be the guide, not theory. They show that the salt bath has a greater influence on the kidney than the simple hot bath.

As to the etiology and the diet, we have laid down carefully studied rules which I think it is unnecessary to weary you with. The character of the diet, how much to give each day and the amount of wine or stimulants is carefully noted.

The Örtel treatment is carried out at Nauheim by sending the patients to walk up the Johannnesberg. As to the etiology, it is impossible to go into that, because the amount of changes which may follow any influence upon the heart is legion. To attempt to associate the lesion with the treatment is impossible. We can only say that the heart is dilated, its propulsive power is diminished. There is, therefore, a back pressure; there is cyanosis, a congestion. If in any way we can dilate the peripheral vessels and allow more room for that blood which is pressed back into the system, we are perhaps going to relieve the heart of its overwork and improve its nutrition, so that the dilatation may end in hypertrophy and compensation.

CLINICAL AND PATHOLOGIC FEATURES OF TWO CASES OF TYPHOID MENINGITIS.

Read in abstract before the Section on Practice of Medicine, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY A. P. OHLMACHER, M.D.

DIRECTOR OF THE PATHOLOGIC LABORATORY OF THE OHIO HOSPITAL FOR EPILEPTICS, GALLIPOLIS, OHIO; PROFESSOR OF PATHOLOGY IN THE CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS.

It will scarcely be necessary to point out, to an audience composed of clinicians and pathologists of large experience, the comparative rarity with which typhoid meningitis is encountered. In fact, the presence of an actual meningitis was so rarely demonstrated in typhoid fever that much doubt existed, only a few years ago, as to the occurrence of this lesion purely typhoidal in its origin. Since 1890, however, several cases of typhoid meningitis have been studied by careful bacteriologic and pathologic methods, so that there can no longer be a reasonable doubt concerning the identity of this complication of typhoid fever.

In a comparatively small number of autopsies on typhoid fever cases, it has fallen to my lot to meet with three instances in which a cerebral meningitis could be demonstrated, and in two of these cases a thorough bacteriologic analysis revealed only the bacillus of typhoid fever as the infecting micro-organism. These two cases were, therefore, looked upon as examples of true typhoid meningitis, and it is to a report on them that your attention is invited. The third case, in which a mixed streptococcus and typhoid bacillus infection was found, has just been reported.[1]

The source of the clinical data for these cases was the records of the Cleveland City Hospital.

Case 1.—Typhoid fever of four weeks duration. Marked delirium in last week preceding death. Autopsy shows usual typhoid lesions of fourth week with acute hemorrhagic internal cerebral pachymeningitis and exudative leptomeningitis. Typhoid bacilli isolated from spleen, mesenteric glands and from meninges.

J. K., Irish, laborer, 25 years old, single, admitted to the service of Dr. A. F. Spurney at the Cleveland City Hospital, Jan. 18, 1896. His father and mother are both alive, and brothers and sisters alive and well. Aside from an attack of measles in childhood, patient does not recall any previous acute illness. He had a suppurating bubo in right groin nine years ago; no further venereal history. A month ago he went to work on an Ohio River boat, making a two weeks' trip which involved a great deal of hardship, and induced several attacks of diarrhea. Two weeks ago he went to Pittsburgh, stayed a week, then returned to Cleveland. Six days ago he again had diarrhea, with a feeling of languor and aching in the legs. Diarrhea persisted till his admission to hospital. The temperature on entrance (afternoon) was 103 degrees F., and the chart shows a fairly typical typhoid curve during the life of the patient, though the fever was unusually high (between 104 and 105 degrees F.) until death. The pulse averaged about 120 beats per minute. The urine was acid, contained a small though constant amount of albumin, and gave the diazo reaction. There were no other records to be obtained except that the patient was continually delirious during the last week of his life, and that he several times passed his urine involuntarily during this period. No suspicion of meningitis was entertained. Death occurred Feb. 3, 1896, seventeen days after entering the hospital.

Autopsy.—Fourteen hours after death. The body, which had been kept in a cool place, that of a man five feet, six and one-half inches in length, and weighing about 125 pounds, showed no significant cutaneous markings. The pleural sacs contained no free fluid. Both lungs were moderately adherent posteriorly. The pericardium contained 90 c.c. of clear fluid, but no other evidences of inflammation. The heart was of normal size and in the normal location. There was no excess of fluid in the abdomen, and the abdominal organs were normally located.

Both lungs were of ordinary volume, with edematous upper lobes, and hypostatic congestion of the lower lobes. The pulmonary pleura, corresponding to the areas of adhesion, was thicker and more opaque than the remainder of this membrane. The bronchial glands were softened and swollen, while the bronchi showed no gross lesion.

The heart was flabby, the surface smooth, the myocardium pale and more than ordinarily friable. The endocardium was intact.

The spleen weighed 220 grams, was swollen, with tense smooth capsule. The pulp was soft and dark red. The kidneys were of normal size. The capsule stripped easily. The cortex was pale, and, relatively, somewhat increased in thickness. The surface of the liver was smooth, the organ pale, the boundaries of the lobules not well defined, and the substance friable. The gall bladder showed no inflammatory lesions, and the ducts were intact. The pancreas contained small deeply injected areas in its substance.

Intestines.—The ileum of the small intestine was almost exclusively the seat of characteristic lesions of its lymph follicles. The solitary glands were generally swollen, and many of them in various stages of ulceration or of healing. The swollen follicles were especially numerous near the cecum. In the upper portion of the ileum the ulcers of Peyer's patches were generally rough, their floors being covered with necrotic debris or with granulation tissue; while in the cecal portion the ulcers were sharply punched out, with clean floors and overhanging edges. Several exceptionally large ulcers appeared in the ileum, close to its cecal junction. No ulcers were found in the appendix. Numerous swollen follicles and a few typical typhoid ulcers averaging half a centimeter in diameter were found in the colon about the cecal region. The mesenteric and retroperitoneal lymph glands were uniformly swollen and softened.

Brain.—The skull cap and the external surface of the dura presented no unusual features. As the dura was carefully stripped back it was found to adhere to the pia unnaturally over the right side of the cerebrum, by means of soft, gelatinous, yellowish flakes, and delicate fibers. This adhesion began about the region of the right Rolandic fissure and increased as the removal of the dura advanced. The gelatinous flakes give place to clots of blood which increased in amount until, over the anterior portion of the occipital lobe, a thick, quite dense mass of clotted blood was found producing a depression, roughly circular in outline, about 4 cm. in diameter, and 1 cm. below the surrounding level at its deepest point. This depression persisted throughout the subsequent handling and hardening of the encephalon. The mass of blood, or hematoma, measured about 120 c.c. in volume. The left side of the large brain was quite free from adhesions or hemorrhage, and no other evidences of this kind were found, except about the base of the brain where a few delicate fibers, not ordinarily encountered, were found between the hard and soft meninges. There was a general edema of the pia mater, and over the right cerebrum this subpial fluid was distinctly cloudy. Under the mass of blood the contiguous pia inclosed soft yellowish flakes, and here the cerebral surface was distinctly reddened. The dural sinuses at the base of the skull contained soft, red, non-adherent blood clots. No excess of fluid, and no inflammatory changes were apparent in the ventricular cavities. Aside from the area depressed by the hematoma, the brain substance presented no gross lesions. The spinal cord was not examined.

Histologic examination.—Portions of the various tissues, aside from the brain, were fixed in Carnoy's chloroform acetic alcohol mixture, dehydrated, cleared in cedar-wood oil, and imbedded in paraffin. The sections were affixed to the slide by the water-albumin method, and stained with various dyes. The cerebellum, medulla and pons were removed by cutting across the crura, and the cerebral hemispheres were separated by a longitudinal median incision. These portions of the encephalon were then hardened in bulk, in a mixture of five parts of 40 per cent. formaldehyde and one hundred parts of water. For histologic study, pieces were subsequently cut from the right cerebral hemisphere, dehydrated, and then handled like the other tissue. In this way the preliminary hardening in bulk fixed the soft meninges in their natural relations. As a general stain, the writer's formalin-safranin was used. Special stains were also made with formalin-methylen blue, carbolic fuchsin, and gentian violet after Gram's process.

---

[1] The Cleveland Medical Gazette, May, 1897.

Lungs.—The pleura was thick and fibrous and there was an increase of inter-lobular connective tissue beneath the thickened pleura, with dilatation of the air vesicles. Deeper down in the lung the alveoli showed only a pronounced congestion of the vessels in their walls. No marked histologic alteration could be detected in the heart, bronchial glands, or spleen.

Liver.—As a whole, the liver substance did not stain as well as usual. There was a slight inflammatory reaction in the connective tissue framework about the groups of lobules. An occasional hepatic cell contained fat droplets, but there was no wide-spread fatty change. Liver sections, colored with safranin, showed an abundance of small brownish pigment granules situated in the protoplasm of the liver cells. When subjected to Perl's hemosiderin test this pigment gave the characteristic Berlin-blue reaction and a wide spread hemosiderin pigmentary deposit appeared in the hepatic parenchyma. Numerous small foci of necrosis (the so-called "typhoid lymphomata") were scattered throughout the liver sections. These foci were especially well seen in sections double-stained with formalin-safranin and formalin-methylen blue.

The kidneys show a moderate degree of parenchymatous degeneration.

Brain.—A wedge shaped piece was cut from the hardened right cerebral hemisphere including a portion of the supra-marginal and anterior parietal gyri with intervening sulcus along with the covering of pia mater. This portion of the cerebrum was anterior to the region depressed by the subdural blood clot. A series of sections from this tissue showed the presence of an undoubted fibrino cellular exudate upon and within the pia. Several quite large masses of coarse fibrin threads lay either upon or beneath the soft meninges. Along with these masses of fibrin were a considerable number of newly formed cells. These cells were mostly gathered into groups of considerable size, and were either large cubical epithelial-like bodies with single vesicular nuclei, or small round cells with single dense nuclei. Small round cells with fragmenting nuclei were only occasionally found in this exudate. These groups of cells were usually situated between the pia and the cortex, especially about a sulcus into which they could be traced along with the extension of the pia. The proliferated cells were also disposed upon the dural side of the soft meninges, though not so abundant as beneath. The abundance of proliferated endothelial cells, with round cells of connective tissue origin, and the scarcity of leucocytes with polymorphous nuclei, gives the meningeal exudate a catarrhal instead of a purulent character, thus corresponding with the gross lesions. No evident alterations were demonstrable in the cerebral cortex, and the blood vessels showed no evidences of endo- or peri-vascular inflammation.

Bacteriology.—During the progress of the autopsy culture media were inoculated, with rigid precaution, from the spleen, mesenteric glands, bronchial glands, and from beneath the pia mater of the right cerebrum in the region of the subdural hemorrhage. From these sources, including the brain, absolutely unmixed cultures of a motile bacillus were obtained. This bacillus gave all the reactions of the perfect typhoid type when subjected to the differential tests now employed for the identification of the bacillus of typhoid fever. The only tests now recognized as of value, that were omitted, were those proposed by Elsner and by Widal, and this omission was occasioned by the fact that the cultures from this case died before the details of these methods had been made available.

A further confirmation of the results of the culture experiments in the case of the brain was obtained in the study of the sections stained with formalin-safranin, methylen blue, carbolic fuchsin and after Gram's method for bacilli with the morphologic and tinctorial properties of *Bacillus typhosus* were found in the fibrinous and cellular exudate and in the lymph spaces of the inflamed soft meninges. No other organisms could be found here aside from the bacilli, which were usually gathered in small groups.

Case 2.—*Typhoid fever with profound coma and delirium. Death in fourth week. Usual typhoid lesions in intestines, spleen and mesenteric glands, with broncho-pneumonia. Extensive purulent cerebral leptomeningitis, ependymitis and dilatation of lateral ventricles. Typhoid bacilli in vast numbers, the only organisms found in meninges.*

The patient, M. S., native born, 46 years old, laborer, married, was brought to the Cleveland City Hospital Jan. 28, 1896, in an unconscious condition and assigned to the service of Dr. A. F. Spurney. The only record of previous history that could be secured was that the patient became ill two weeks before entering the hospital. Temperature on admission (afternoon) was 103.2 degrees F. The patient was alternately delirious and comatose and did not regain consciousness during stay in hospital. Other nervous symptoms were not recorded. The temperature ranged from 102.2 to 103.8 degrees for the first seven days, with evening exacerbation. On the eighth day the fever rose sharply to 104.6 degrees and remained above 104 degrees for the next two days and then fell by daily stages till, on the thirteenth day after admission, it reached 100 degrees and death occurred. The urine was acid, of an average specific gravity of 1018, contained a small amount of albumin, and gave the diazo reaction.

Autopsy.—The autopsy was performed February 10, eighteen hours after death, and the corpse had been kept in a cool place. The body was wasted, 197 cm. long and approximately fifty-five kilos in weight. The skin was generally pallid except for a moderate postmortem lividity of the dependent parts. The mucous membranes were very pale. The abdomen was moderately and symmetrically distended. No free fluid existed in the peritoneal cavity, which was negative in other respects. The left lung was moderately adherent, especially about the posterior aspect of the upper lobe, and 120 c.c. of clear serous fluid was present in this pleural sac. A like amount of similar fluid existed in the right pleural cavity, though the lung on this side was not adherent. Both lungs were of good volume. The pericardial sac contained 30 c.c of clear yellow fluid. The heart weighed 260 grams and, aside from an increased pallor and friability of its myocardium, presented no changes. The aorta showed a few desseminated plaques of recent sclerosis about its origin. The right lung, weighing 650 grams, was generally congested and edematous. Small, dense, friable, non crepitant, deeply injected areas were scattered through the lower lobe. The left lung weighed 550 grams and, aside from a moderate thickening and opacity of the visceral pleura, corresponding to the region of adhesion, was only congested and edematous. The bronchi were filled with frothy, muco-purulent, thick fluid, and their mucous lining roughened and deeply injected. The bronchial glands were black, swollen and soft. The larynx showed no ulceration.

The liver (1820 grams) had a smooth surface and was generally of a lighter hue than normal. The substance tore when the capsule was stripped and was less firm than usual. On section the surface was quite pale and close inspection showed the pallor to be especially marked at the periphery of the lobules, while the central portions were more deeply colored. The portal and hepatic veins were not unusually injected. The gall bladder contained a small amount of yellow bile. No distinct evidences of inflammation could be detected in its lining and its ducts were intact.

The spleen was swollen to almost twice the ordinary size and weighed 300 grams. The pulp was dark red and very soft.

The kidneys together weighed 250 grams. The cortex was pale, its vascular markings unduly prominent, and it relatively somewhat increased. The urinary bladder was about half full of urine. The pancreas contained distinct ecchymotic areas, which were not, however, distinctly softer than the general substance. The stomach was free from gross lesions.

Intestines.—The typhoidal intestinal changes were quite closely confined to the last meter of the ileum. Here swollen solitary glands, punctate ulcers of the solitary follicles and large oval ulcers of Peyer's patches were abundant. A few of the ulcers had clean bases but in most of them the floor was rough and contained either sloughing or granulation tissues. An especially large, round, ragged ulcer was located in the ileum near the cecal valve. No ulceration was evident in the appendix and this held true for the colon, although a few solitary follicles in the cecum were swollen. The mesenteric and retroperitoneal glands were much swollen, very soft and dark hued.

The brain weighed 1420 grams including exudate. The skull-cap and exterior of the dura were not visibly altered. The dura stripped readily over the dorsum of the cerebrum. At the base of the brain a few recent subdural adhesions existed. There was no marked excess of subdural fluid. On its removal the brain looked dull and lusterless, with certain areas more

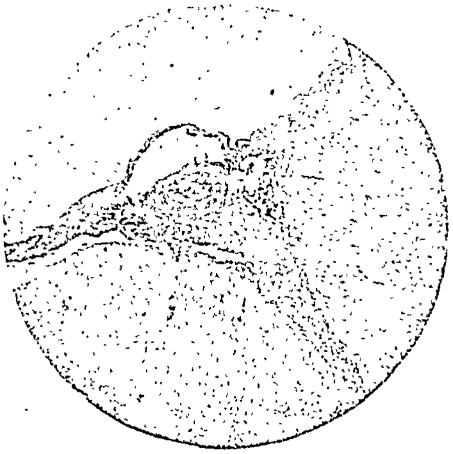

FIG. 1.—Typhoid leptomeningitis. Case 2. Portions of two cerebral gyri with intervening sulcus, and meningeal covering. The meningeal membrane is filled with inflammatory exudate. A small branch of the middle cerebral artery is seen in cross section, with its endarterritis.

Photographed with Leitz obj. 2, oc. 1.

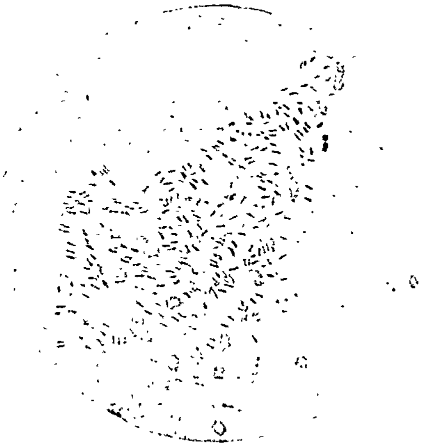

FIG. 2.—A portion of the arachnoid membrane from the same section as Fig. 1, showing the numerous typhoid bacilli.

Drawn from a photograph with Leitz obj. one twelfth, oc. 4.

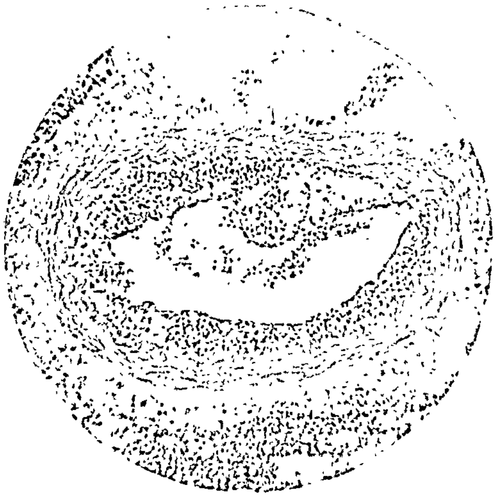

FIG. 3.—From same series of sections as Fig. 1. One of the branches of the middle cerebral artery showing the acute endoarteritis. Note the inner bounding membrane (endothelium), and the numerous small cells between it and the intima. Some of the small cells are also seen within the endothelial lining.

Photographed with Leitz obj. 7, oc. 4.

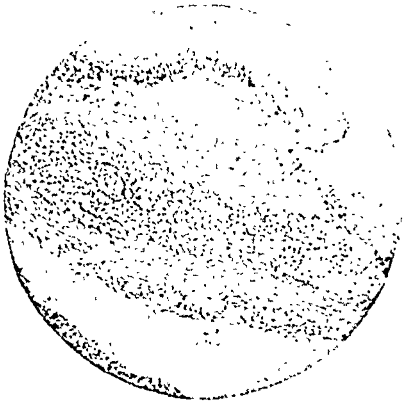

FIG. 4.—From another series of sections of the cerebrum in case 2. A branch of the middle cerebral artery showing the complete obliteration of the lumen by the endarteritis.

Same power as Fig. 3.

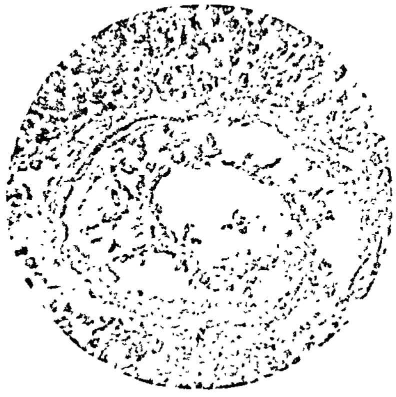

Fig. 5.—Same section as Fig. 1. A minute arteriole of the middle cerebral artery showing the endarteritis. The endothelium is raised well into the lumen of the vessel. There is a moderate sub endothelial cellular proliferation, and a few cells lie within the lumen.

Leitz obj. one-twelfth, oc. 4.

opaque than others. The venous channels were turgid with dark red blood. Along the lateral aspects of both cerebral hemispheres broad lines of yellowish material accompanied the vessels of the pia mater. This appearance was especially prominent along the Sylvian and Rolandic fissures. At the base of the encephalon a milk-white, comparatively thin, turbid fluid filled the larger spaces left as the leptomeninx stretched across one of the larger clefts, particularly in the fissure dividing the two cerebellar lobes. On removing the cerebellum, pons and medulla, by cutting through the crura, no excess of fluid escaped, and, except for a slight injection of its lining, the fourth ventricle showed no change. The cerebral hemispheres were separated by a longitudinal median section and as the third ventricle was incised, a thin, white, turbid fluid escaped. This fluid continued to flow from both lateral ventricles, as they were exposed by the incision, until a quantity measuring 40 c.c. in volume had been obtained. The velum interpositum and choroid plexuses were deeply reddened and the ependyma was also reddened, with numerous hemorrhagic ecchymoses. The cerebral cortex was rather soft, but it was impossible to decide upon the existence of an actual inflammation of its substance. The meningeal exudate was present about the cervical spinal cord, though no further examination of this organ was made.

Bacteriology.—The turbid fluid from the meninges and from the ventricles was examined in fresh preparations and found to contain a few red blood cells, abundant pus cells, a few desquamated epithelial cells, protoplasmic and myelin debris, along with hosts of plump bacilli, some of which were actively motile, while the majority were engaged in an exaggerated Brownian motion. Stained smears from this fluid showed the same cellular elements, along with the bacilli. No other micro organism was found in these preparations.

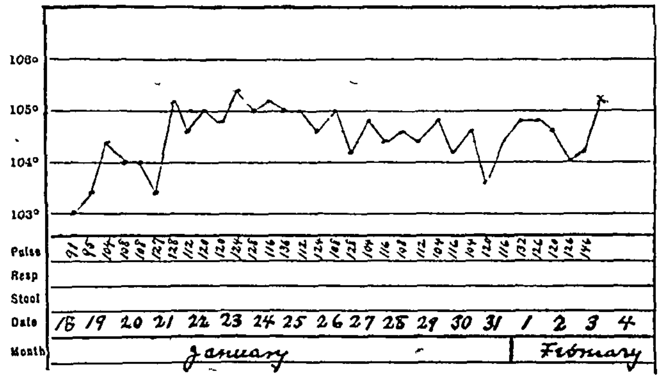
Agar dilution cultures, by the method of Banti Grosglick, were prepared from various sources with great care. From the spleen, mesenteric glands, bronchial glands, and from beneath the pia mater, perfectly pure cultures of a bacillus were secured. This bacillus was exhaustively examined by the differential tests proposed for identifying *Bacillus typhosus* and found to react typically in all instances. The culture from the leptomeninx is still in my possession and has been used as a stock culture for making the Widal serum test for typhoid fever, since it gives a rapid and complete agglutination reaction with typhoid blood. It has also been grown beside the colon bacillus, on Elsner's medium, on several occasions, and here found to comport itself typically. From one of the consolidated areas in the right lung the typhoid bacillus and *Staphylococcus aureus* were isolated. No growth developed from the heart's blood. The colon bacillus was obtained from the urine in the bladder.

Sections from the brain, stained with formalin safranin, methylen blue and carbolic fuchsin, exhibit countless myriads of bacilli in the soft meninges and in the meningeal exudate, similar in morphology to those obtained in the cultures. In sections stained by gentian violet, after Gram's process, the bacilli discharged all traces of color. The bacilli were crowded in dense lines in the lymph spaces of the meningeal connective tissue, or scattered thickly among the cells comprising the exudate.

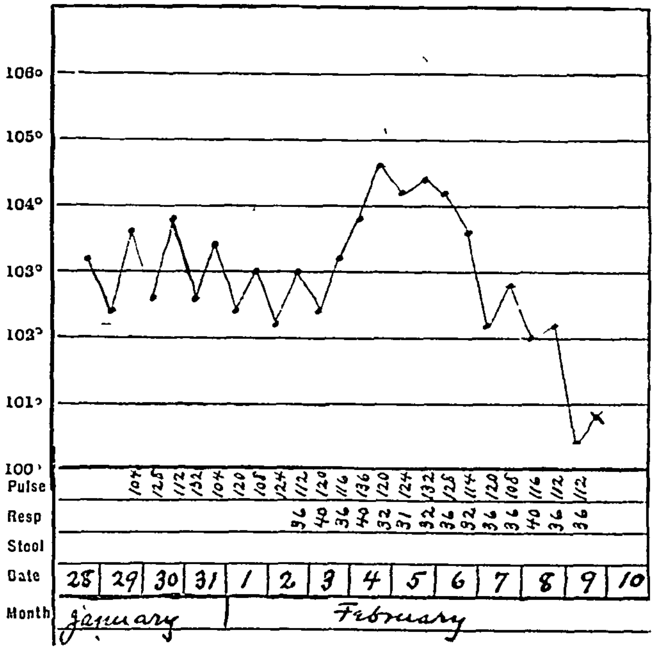
In the exudate filling the pulmonary air cells, hosts of bacilli, corresponding precisely with those in the meninges, were scattered about, with here and there an occasional large group of micrococci.

Histologic Examination.—The main interest from the histologic standpoint naturally centers in the study of the brain lesions in this case. Sections from three portions of the encephalon, including the leptomeninx, have been examined, viz.: From the cerebrum anterior to the Rolandic fissure (including a portion of the ascending and inferior frontal gyri with the inferior precentral sulcus); from the posterior occipital lobe of the cerebrum; and from the postero-inferior lobe of the cerebellum. The microscopic appearances in the meninges of the anterior cerebral and cerebellar regions were indentical. A layer composed of abundant and closely packed leucocytes with fragmenting nuclei, and of epithelial cells with single nuclei held together, in places, by a delicate fibrinous reticulum, was everywhere present between and upon the layers of the soft meninges. The exudate was especially abundant beneath the pia, and followed the sulcate extension of this membrane to its innermost depth. In the occipital lobe the exudate was very much less abundant, and in its character resembled very closely that found in Case 1. Here the proliferated and desquamated endothelial cells predominated while the pus cells were diminished. Here also the arterial changes now to be described, were absent. The existence of a parenchymatous cerebritis has not been definitely decided by the microscopic examination, since there is reason to suppose that the technique employed in preparing the brain substance for section was not best suited for preserving fine structural alterations.

This brings us to a consideration of another important feature in connection with this case, a feature of such interest that it merits a further and fuller description than can be given here, and I hope to be able to soon give a more detailed account of it. I refer to an exquisite and widespread *acute endarteritis* affecting the smaller arteries of the pia in both the anterior cerebral and the cerebellar regions; in other words, an endarteritis involving at least the branches of the middle cerebral and anterior cerebellar arteries. The process affects both the medium sized and smaller arterial branches, and varies from a partial to a complete obliteration. Serial sections from one of the larger vessels showed the advance from a partial to a complete obliterating endarteritis. In the more minute twigs the change most frequently results in complete obliteration, and the newly-formed tissue fills the lumen of the vessel. The study thus far made of this condition seems to point to the conclusion that the endothelium of the intima is raised from its bed and forced into the lumen of the vessel by a subendothelial exudate; at least a distinct membrane with fusiform nuclei can be found in the vessels in which the obliteration is not complete, bounding the new cells internally; and where the occlusion is complete a central core of cells with laterally compressed nuclei seems to be the same membrane forced into a compact mass. Two distinct kinds of small cells, both poor in protoplasm, are to be found in the endoarterial exudate, one with nuclei composed of compact deeply staining chromatin and engaged in one or another of the stages of indirect fragmentation; while the others, comparatively less numerous, are slightly larger and possess single nuclei with the chromatin more diffused. These small cells do not differ in structure from the *pus cells of the general extravascular meningeal exudate*, and are united by delicate protoplasmic fibers which seem to bind the cells together by a delicate reticulum, though they are often



Case 1. Typhoid meningitis.



Case 2. Typhoid meningitis.

separated some distance from each other. These cells are generally located between the membrane looked upon as the displaced endothelium, and the intima, though they also occur within the bounding membrane. This colony of new cells does not extend beyond the elastic layer of the intima, which, together with the muscularis, seems to be absolutely intact. A peculiar feature of this intravascular alteration was the absence of the bacilli which were so abundant elsewhere in the meninges. The most careful search has failed to show bacilli within the larger arterial branches. An occasional bacillus, lying in a small arterial branch which was imbedded in a mass of pus, was regarded as accidencally transplanted during the technical manipulation. The bacilli are abundant about the arteries, even to the extent of invading the perivascular lymph space, but they seem to be effectually barred by the muscular media. Very few red blood corpuscles are present in the affected arteries, while the corresponding venous channels are choked with blood elements.

The softness of the cerebral cortex noted in the fresh gross specimen was doubtless closely connected with this arterial disease.

The liver showed a wide-spread fatty infiltration and a large amount of intracellular pigmentary deposit which gave the hemosiderin reaction. No focal necrosis was to be found in the liver. Hemosiderin was also present in the spleen and bronchial glands, but entirely absent from the kidneys.

The consolidated areas from the right lung exhibit a pronounced exudate composed of leucocytes and epithelial cells lying in the pulmonary alveoli.

In viewing these two cases from the clinical standpoint the insignificance of the symptoms pointing to the meningeal disease is the most striking feature, and corresponds to the majority of the cases of typhoid meningitis recorded. To bring out this point and to illustrate certain features in the pathology of this complication of typhoid fever, the following summary of the literature is presented.

The Index Catalog of the Surgeon-General's Library contains but five references to meningitis occurring in the course of typhoid fever, in the period from 1855 to 1887, and as no trustworthy bacteriologic examinations were made in these cases they can not be looked upon as typhoid meningitis in the strict sense.

In the course of a study of meningitis, Neumann and Schaeffer[1] (1887) found an extensive purulent leptomeningitis in a woman brought to the hospital unconscious and who died in a few hours without furnishing any history. No lesions of typhoid fever were found, but pure cultures of a bacillus were obtained from the meninges and these, the authors were led to believe, were of *Bacillus typhosus*, from the general characters and from the positive results of the potato and fermentation differential tests. A very similar case was reported soon after by Adenot,[2] in which a woman presented profound symptoms of cerebral infection and died in eight days. Absolutely no typhoidal lesions were present in the intestines, spleen and mesenteric glands, but from the sero-purulent exudate in the soft meninges a bacillus resembling the typhoid organism was obtained. The only differential test here applied was the growth on potato, and we now know that this is not sufficient to identify the bacillus of typhoid fever. The case recorded by Balp[3] also belongs in the same category with those of the authors just noted. He found a diffuse purulent meningitis in a patient dying five days after a fracture of the skull, and in the exudate a bacillus resembling the Eberth organism was found, together with a species of diplococcus. The phenol and indol tests are all that Balp mentions having used for differentiation.

A case of meningitis occurring in the course of typhoid fever was described by Kamen,[4] in 1890, in a soldier who entered the hospital after having been ill for five days. A severe headache set in three days later, followed by delirium and unconsciousness, and death occurred eight days after admission to the hospital. Aside from acute splenic tumor and a single typhoid ulcer near the cecal junction of the ileum, the postmortem examination showed an extensive purulent leptomeningitis. The cultures obtained from the spleen, mesenteric glands and meninges were identical, though only the potato test is mentioned as having been employed for identification. The following year Fernet[5] reported the case of a woman who developed headache, delirium, strabismus, exophthalmus, retention of urine and irregularity of the pupils in the course of a typhoid fever. At autopsy the characteristic changes of typhoid were found in the abdominal cavity, and a diffuse serous meningitis was also present. It is claimed that typhoid bacilli were isolated from the meningeal fluid, though no mention is made of special tests. Silva[6] likewise observed at autopsy in a female epileptic, 10 years of age, a serohemorrhagic leptomeningitis with a lobar pneumonia and the ordinary evidences of typhoid fever. Typhoid bacilli were isolated from the meninges and carefully identified. Still another case was reported by Honl,[7] who found a diffuse purulent leptomeningitis in a 21 year old woman who died in the course of typhoid fever. An exhaustive differential examination showed the only bacterial species obtained from the meningeal exudate to be *Bacillus typhosus*.

Cases essentially similar to those just noted have been reported since 1892 by Vincent,[8] Hintze,[9] Mensi and Carbone,[10] Stühlen,[11] Tictine,[12] Kühnau[13] and a second one by Kamen.[14]

Tictine reported two cases which came under his observation and he also produced a purulent meningitis in animals by means of subdural inoculations with typhoid cultures. The second one of his cases differs from all the others in that the patient was perfectly conscious during the last week of his life.

Profound unconsciousness, delirium, coma and often retention of urine are the symptoms most often described in these cases. Other symptoms which might suggest an actual meningitis are usually insignificant and can scarcely be looked upon as of diagnostic import To this rule, however, the case mentioned by Mensi and Carbone is a notable exception. Their patient was a girl 6 years of age who had been ill nine days before entering the hospital. The patient ran the course of a moderate attack of typhoid fever reaching the stage of apyrexia four weeks after coming to the hospital. Four days later a violent chill occurred with intense headache and a temperature of 39.2 degrees C. Delirium, opisthotonus, contractions, amblyopia and dilated non-resposive pupils were successively noted, together with a herpes labialis, paresis of right face and retraction of abdominal wall. Great prostration followed and death occurred four days after the onset of this relapse. The autopsy showed a fibrino-purulent cerebro-spinal meningitis with dilatation of the lateral ventricles, and a bronchitis of the medium and smaller bronchioles. Numerous typical typhoid ulcers in the stage of healing were found in the ileum and colon; the mesenteric glands were swollen and soft and there was softening of the spleen. A thorough bacteriologic examination of the meningeal exudate resulted in finding typhoid bacilli as the sole bacterial inhabitant.

INTERRUPTIONS IN METABOLISM.

Presented in the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY I. N. LOVE, M.D.

EX-PRESIDENT MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

ST. LOUIS, MO.

In the term metabolism we mean to express the group of phenomena whereby organic beings transform foodstuffs into complex tissue elements, and convert complex substances into simple ones, in the production of energy; in other words the entire process of tissue building, which includes the proper throwing off of unused débris and the elimination of excretory matter, the complete scheme of nutrition, tissue making, production of energy and the elimination of waste matter.

After an individual has secured his growth, if no mistake has been made, we have an animal mechanism which, under proper conditions, should be good for seventy or eighty years of continued work. Any break in the continuity of this mechanism can safely be interpreted as due to an interruption in metabolism. This interruption may be and generally is at first a light one and if taken promptly may be easily corrected. If this be neglected and permitted to continue we will sooner or later probably have a condition irremediable. All of the hopeless organic diseases, such as Bright's disease, diabetes, heart disease, including the various forms of carcinoma have such a beginning.

These breaks in the continuity of the nutritive process—metabolism—no matter how light or severe, result in the development or retention of poisons, begetting the conditions which can best be expressed by the term "gout."

The popular impression regarding gout as being related only to the joints is now known to be wrong.

The manifestations of gout are as manifold as the individuals. In one we may have it assume the form of a so-called dyspepsia, a catarrh of the stomach, a neuralgia, or that even which stimulates neuritis, rheumatic disturbances of the joints, a nerve poisoning with marked symptoms of nervous prostration, asthma, hay fever, etc., all along the line to the extreme limit of apparent organic disease.

Years ago Sydenham said, "gout is the lord of disease and the disease of lords," but it is more, it is the universal disease, including pauper and patrician. We know that 90 per cent. of the so-called rheumatism is gout, surely all of it, save the pronounced acute inflammatory variety suggestive of an infection, and by the way the infection was invited or made possible by the metabolic interruption, by the gouty condition. A very large number of the disturbances of the mucous membrane, such as bronchitis and cystitis at all ages, but particularly in advancing age, as well as skin affection like acne rosacea, the red nose, usually attributed to the excessive use of alcohol, when as a matter of fact the victims of it are often abstemious, and in many cases even ascetics, poorly fed and never cheered by the wine when it is red or any color.

Heredity is an important factor in all those cases. From generation to generation the family habit of "going off at a tangent, as it were," has been developed in the organs connected with metabolism. What are the prime causative factors in those metabolic disturbances? The answer is, errors of diet and checking of elimination.

The dietetic errors may be either too little or too much food, or food of an improper character. Faulty elimination may be due to improper clothing, chilling of the surfaces, neglect of the excretory organs, uncleanliness of the skin, carelessness as regards the proper emptying of the rectum and colon (a cultivation of the constipation habit), a neglect of renal flushing in not drinking a sufficiency of pure water, and bodily inertia. It is our duty to guard our patients against these mistakes in metabolism, by impressing them with the importance of proper hygiene, proper eating and drinking, and above all, with the value of work. True it is that a man can not live healthy nor long unless he earns his living "by the sweat of his face." We must all be "sons of toil," as well as "Sons of Temperance," if we would live a long life and a happy one. Indeed well may we say, "blessed be drudgery."

When these breaks in the continuity of the nutritive functions—the processes of metabolism, do occur they should be promptly corrected, for they invite infections, in that the system is put off its guard (so to speak), and tend toward dangerous organic diseases. Prompt attention to and correction of diet is essential; but in the matter of diet, as well as in every thing else, each individual is a law unto himself.

"What is one man's meat is another man's poison," in more ways than one. Let us in these cases of gout, as in all other diseased conditions treat the individual rather than the disease.

There are numerous cases in which a red meat, a roast beef diet, will produce such a metabolic interruption as to amount to a terrific gouty explosion if long continued. Other cases do better on a meat diet. On general principles sugar and starches should be eliminated from the diet list, but occasionally anemic victims of gout call for cereal food of the coarsest character.

Milk is almost the ideal food for these cases, indeed for all cases with crippled powers of digestion, assimilation and elimination. We should give immediate aid to elimination, through judicious stimulation and regulation of all the excretory organs, while the establishment of proper equilibrium of physical exercise and rest is demanded.

Physiology tells us that tissue building, repair and health depend on the proper glandular activity, and that the poison-resisting property of the human body exists in the blood. It is now well established that the element of the blood which possesses this property is the leucocyte, and that if the leucocytes are of sufficient number and possess their normal vitality and strength, the pathologic or toxic condition will be overcome and health restored.

Nuclein, when formed in the blood, is the result of the action of the leucocyte upon the proteids. When introduced into the organism it acts in two ways.

1. It immediately excites the action of each leucocyte, causing it to proliferate or break into nuclei, producing leucocytosis, and the fundamental axiom of physiology is, the more active the leucocytosis the greater the vital resistance. 2. It furnishes material to the leucocyte which, under a depressed vital condition, it is unable of itself to construct from the proteids, while it so strengthens and increases the number of leucocytes that it overpowers the toxic germs with which it may come in contact. Thus it may be seen that protonuclein, which is a combination of all the nucleins of the body, is the true tissue builder and antitoxic principle of the organism.

Protonuclein is derived from the lymphoid structures of healthy animals without the use of any chemical. By a delicate mechanical process the nuclein is separated without changing the condition in which it exists in the organism.

Reliable information has been given that protonuclein is prepared from the following glands: 100 pineal glands and pituiary bodies of the brain, 100 salivary glands, 100 thyroid glands, 100 pancreatic glands, 100 inner linings of the stomach, 100 Brunner's glands and Lieberkühn's follicles, 100 thymus glands.

These are derived from the pig, with the exception of the brain, which is obtained from the ox. The methods and means to secure glands from healthy animals are carefully supervised by expert observers. All of the inert tissues are separated from the glands, after which they are passed through a disintegrating machine, and quickly dried by forcing warm air through them by a specially prepared machine, so rapidly that no change can possibly take place, for the vapor of benzoin is passed upward through the desiccator, enveloping the cellular elements and preserving them intact. They are then exhausted with ether, to remove any fatty matter, and again thoroughly dried by the same process, and the portion of the gland that is richest in nuclein, which consists of a little over one-third of it, is then separated from the whole mass by special machinery. It should be borne in mind, that the portion of the gland containing the nuclein is very readily converted into a powder, and consequently easily separated from the inert matter by sifting.

Surely animal therapy is physiologic medication, and whether we administer such agents as protonuclein, which is the active principle in regulating metabolism, or antitoxins, which oppose infectious diseases, we are working along the same lines. The former is the most physiologic and the elementary risk is the least involved. When we can administer remedies which have a physiologic basis, and are followed by the most satisfactory clinical results, we are pursuing the scientific course.

The very satisfactory results following the administration of protonuclein in so many seemingly varying diseases are explained when we realize that these diseases, whether stomachic, neuralgic, rheumatic, stoppage of growth, obesity, organic or infectious, are all due to conditions produced by the same cause, "interruptions in metabolism." In brief, protonuclein is the ideal remedy for the reëstablishment of the proper equilibrium of the metabolic functions; and three years constant use of the remedy, followed by almost uniform success justifies a continuance of the agent which is the key-stone in the arch of animal therapy.

BLOOD-LETTING AS A THERAPEUTIC REMEDY, BASED ON A REPORT OF TWENTY-SIX CASES.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY J. W. HOFF, M.D.
POMEROY, OHIO.

I desire to present a report of successful issues from the use of venesection as a remedy in the treatment of various cases met with in a continuous practice of over fifty years; not for the purpose of adding anything new to our knowledge of this subject, but to call attention again to this most valuable remedy which modern therapeutists seem inclined to relegate to a past age.

In the year 1844, with my preceptor, I was called to see a woman who had been in a stupor or coma simulating death for six hours, and all efforts of her physicians had failed to revive her. Noticing that the basilic and cephalic veins at the bend of each arm had many scars over them, I suggested that she be bled, as she had evidently been bled many times before for the same purpose. My preceptor Dr. Eyster, immediately opened the basilic vein and set me to rubbing the hand and arm to start the blood to the opening in the vein. After eight or ten minutes a full stream of blood leaped forth and when about two ounces had been withdrawn the woman awoke with a cry which frightened her attendants. The bleeding was stopped, and in ten minutes more the woman was cheerfully talking with the doctors, and told us she had been bled a great many times before by physicians in Baltimore, where she formerly lived, for the same trouble, and that bleeding seemed to be the only effectual remedy for restoring her to consciousness.

In 1845 I heard Prof. Meigs describe in the Jefferson Medical College a case quite similar which had just occurred in his practice, in which, after using all other remedies without avail, bleeding was resorted to with almost immediate relief.

In May, 1846, I located in Ripley, Va., and the day I arrived in the town I was called to my first patient, a man 40 years of age, in delirium tremens, with the most violent convulsions I ever witnessed. By the help of three strong men I was able to control him until I had opened the basilic vein and drawn three pints of blood. The convulsions soon ceased and, after tying the arm, I left my patient in the care of an attendant and went to my hotel. Two hours later I was called by the attendant saying my patient was dead. Hastening to his room I found he had loosened the bandage from his arm and had bled in his sleep until he fainted. I soon tied up the arm and revived him, and took from the bed one-half of a tin washbasin of blood clot. I remained with him until he was again comfortable, and the next morning he resumed his accustomed duties as clerk of the court, saying he had not felt better in years.

Two weeks later I was called to see an attorney, 23 years of age, who had fallen in the street from sunstroke. I found him unconscious and breathing very hard, face flushed and temple veins very prominent.

I immediately took from two to three pints of blood from the cephalic vein, when consciousness returned; I then applied cold water to the head and enjoined rest until evening. He, however, disobeyed my instructions and walked two squares to his office, but without harm, as he was able to attend to his usual business the next day in the court room. I would not dare bleed to this extent now, as I would probably be prosecuted for malpractice.

In June, 1846, I was called to see a lady 32 years of age who had a severe attack of bilious fever. She had had similar attacks the three preceding years and each time was three months in recovering, besides being badly salivated. I promised to have her about within ten days and without salivating her. I found her with high fever and delirious. After bleeding her to the extent of two pints the delirium ceased. I then gave her an emetic of ipecac, and followed this by twenty grains of calomel and ten grains of quinin washed down with a pint of very cold well water. The lady's husband protested and said the calomel would surely salivate his wife and she would die. I assured him that she would not be salivated. I left my patient comfortable that evening, and when I called at eight o'clock the next morning she was sitting up in bed eating toast and tea. There had been profuse sweating during the night and the physic had operated effectually; the pulse was normal and there was no fever. I gave no more medicine but ordered rest and diet. On the following morning the patient was able to sit with the family at the breakfast table, to the great relief of her husband. She was literally well and was not salivated. I am sure the thorough bleeding relieved the congested liver and contributed greatly to the recovery.

I treated a number of similar cases during the next three months with like results. There were eight deaths in the same township that year from this disease, but none of them were bled or treated by me.

In November, 1846, I was called to Ravenswood in consultation with three other physicians to see a boy 13 years of age, with pseudomembranous croup of three days' duration. The boy was cyanosed and rapidly passing into a condition of asphyxia. After learning of the preceding treatment and seeing no good results, I advised bleeding freely as a last resort. My advice was not taken, the other members of the council maintaining that it would do no good and would probably hasten death. After leaving the council and before I had reached the hotel, the boy's father came after me and urged me to return and bleed the boy, as the other doctors had gone home and left his boy to die. I reluctantly returned with the father, had the boy stripped and put in a warm bath, and bled him from the arm in the bath until near fainting; I then took him from the bath and wrapped him in a warm blanket and laid him in bed, where he breathed freely and easily. He went to sleep and slept two hours without coughing or hoarse breathing. When he awoke it was with a hoarse cough and flushed cheeks. I ordered a new bath and opened the same vein again and bled him to fainting. We removed him from the bath and put him in bed as before, and from that hour there was no more hoarse breathing or metallic cough. The boy soon convalesced to perfect health and lived to be a prominent banker and useful citizen. No other medicine was given in this case except mild expectorants. For ten days he spoke only in whispers and coughed up quantities of false membrane and tube-casts.

In the year 1857 my oldest son, 3 years of age, and a nephew of about the same age, took pseudomembranous croup at the same time, and for three days and nights I gave them constant attention and used every means at my command to relieve them, but all medical treatment utterly failed and my nephew died on the third night. My son was so nearly dead that he could not be laid down, and was badly cyanosed and gasping for breath. I determined in spite of my family and friends to bleed him. I bled him in an erect position in the arms of his uncle, taking about two ounces of blood, when he fainted. I then laid him in a horizontal position and revived him, and when he recovered he breathed easily and the cough was gone. The inflammation and fever subsided and the formation of the membrane ceased. This resulted undoubtedly because of the revulsive effect of the blood-letting. The child had a good convalescence, but for eight or ten days could not speak above a whisper and coughed up great quantities of membrane. He is alive and well today, and so far as anyone knows he never experienced any bad effects from the treatment.

In 1850 I was called to see a gentleman 65 years of age who had been sick with the measles for a week, and the measles would not come out. He had taken quantities of teas and toddies, been steamed and otherwise tortured, and was then delirious, with high fever and great blood pressure. There was evident congestion of the brain and lungs. After bleeding him two and one-half pints he fainted, and when he revived he was conscious and asked for a drink. After drinking a pint and one-half of very cold water the fever subsided and he went to sleep. He had not slept more than twenty minutes when the measles came to the surface and in two hours they came out so abundantly that he could not see; he was kept under mild cathartics and diaphoretics and made a good recovery without further treatment.

In 1851 I was called to see a lady 26 years of age who was having a severe attack of puerperal fever with peritonitis of about six hours' duration. I bled her until the tongue blanched, taking about two pounds of blood; gave twenty grains of calomel with opium and ipecac, and ordered turpentin and camphor liniment over bowels. The next morning the patient had slight fever, no pain, but some tenderness over the bowels. This patient recovered entirely in eight or ten days. I had treated two other women having the same difficulty just previous to this case but without bleeding, and lost both cases. I have never lost a patient with this fever that I have bled freely within six hours of the inception of the disease.

In 1852 I was called hastily to see a gentleman who had had a stroke of apoplexy. He was unconscious and struggling in spasms. I bled him a pint and one-half, when he revived and soon recovered without any other treatment. I have bled many for the same trouble soon after the attack, and with uniform good results.

In the fall of 1853 I was called to see a lady 20 years of age in her first labor. I found her in violent and continuous spasms of eclampsia. I gave her chloroform with but slight relief, and tried to deliver the child but found insufficient dilation. I bled her nearly two pints when convulsions ceased, but the patient could not be aroused. No labor pains were apparent, but the cervix relaxed well after the bleeding. I turned and delivered the child still-born and it could not be revived. The patient had no more spasms or fever, but lay for thirty-six hours in a profound stupor. She then aroused in her right mind, but had no recollection or knowledge of what had taken place after the first spasm. She experienced no secondary bad effects and her next confinement was normal.

In 1864 I was called to see Mrs. S——, aged 22, in her first labor. I found her in a violent attack of eclampsia. I immediately bled her to the amount of two pints when the spasm ceased. In a few hours I delivered her of a healthy child. The mother had no more spasms and a good recovery.

In 1847 I was called to see a young lady who was suffering with a severe attack of angina pectoris and found her in great distress and almost asphyxiated, being unable to lie down. I bled her freely in a sitting position until spasms relaxed. I gave her no further medication but enjoined rest. In a few days she regained her usual health.

In 1849 I was called to see a young man 15 years old who was having a violent attack of cerebrospinal meningitis. He was wildly delirious, spine stiff and curved backward. I bled him to the verge of syncope, applied hot packs all along the spine and neck and over the heart, and gave a large mercurial purgative combined with opium. The rigidity of the spine gave way in twelve hours after the bleeding. The delirium was also relieved at the same time, and the young man had a good but slow convalescence.

In 1848 I was called to see a young woman 22 years of age who had double pleura pneumonia in its worst form. I bled her to the verge of fainting, relieving the congested lungs and pain, then gave her the usual treatment for pneumonia and she was up in eight days' time. I am confident I have cut short many such cases by bleeding freely in the first stages of the disease.

In 1854 I was called to a patient 30 years of age who was having a violent attack of inflammatory rheumatism. He could not move his limbs or body in bed, and the joints were badly swollen and inflamed. I bled him until his tongue turned pale, and then gave him twenty grains of calomel, two grains of opium and two grains of ipecac. He perspired freely during the night, and by morning was greatly relieved of pain. He gradually improved for ten days and could then walk the streets by the aid of a cane.

During the years 1846 to 1856, I was frequently called to treat a gentleman about 26 years of age who had frequent attacks of epileptic convulsions. After failing to relieve the convulsions by treatment, I found I could succeed by opening a vein and starting the blood to flowing freely. I did not usually take more than six to eight ounces and often not more than four ounces. The flow of the blood seemed to equalize the circulation, thereby relieving hyperemic conditions in the brain.

In 1852, while crossing a river on horseback, I was stricken with sunstroke. I was blinded instantly with an intense pain in my head. My horse carried me home and stopped at my door. My wife met me and led me into my office where I lay down on the floor and had cold applications made to my head. but getting no relief I had my left arm tied up and by feeling I opened the basilic vein and bled myself until the pain in my head ceased. In a half hour I was able to sit up, and the same evening walked out in town with no pain in my head nor other bad feelings. I am confident I lost from three to four pints of blood and had no unfavorable secondary effects.

In 1856 I was called to see a gentleman aged 20, who was having a violent attack of brain fever. He was wildly delirious with a high fever. I bled him to nearly fainting, applied ice to the head and the delirium subsided. I gave a mercurial purge with sedatives and he made a good but slow recovery. The same year I was called to see a lady 25 years of age, having a severe attack of acute pleurisy. I bled her nearly a quart and the pain was very soon greatly relieved. The pain was further relieved and cure resulted with only a hop and vinegar poultice to the side.

In 1863 I was called to see Mrs. A——, aged 30, who had acute catarrh of the head and congestion of the lungs. After bleeding her to near fainting, the relief to head and lungs came almost immediately. The cough and blood-mixed sputa were greatly lessened. I afterward used the customary treatment and the patient recovered rapidly and was up and around the house in a week's time.

In 1854 I was called to see a gentleman 54 years of age, weighing about 250 pounds who had had a stroke of paralysis the previous day. Other physicians had been in attendance but had failed to relieve him. I found him completely paralyzed so that he could not make any voluntary movement. He could not swallow anything. Finding that he had not been bled, I advised bleeding, and after drawing over three pints of blood he was bathed with strong stimulants. In an hour he opened his eyes and two hours later drank a little water. Four hours after bleeding he was given a large dose of calomel. Next morning he was able to make slight movements of the voluntary muscles of his limbs. I bled him again, one and one-half pints, and left him to return thirty hours later, when I found him able to swallow fairly well, to move his limbs considerably but unable to speak. In three weeks this man had so far recovered as to be able to walk about his house and yard, and in six weeks he was practically a well man with the exception of his voice which he never recovered. He lived for twelve years and died of dropsy.

In 1858 I was called to see a lady 30 years of age, who had been violently insane for a week. She had to be guarded day and night to prevent her from killing her own friends; she seemed determined to kill her husband. I secured her confidence and persuaded her that she had a bad headache (which was true) and proposed bleeding her for it. She willingly consented. I bled her in a sitting position until she fainted, taking about one quart of blood. She soon revived and was calm and quiet; and after two or three hours' sleep awakened rational. She then consented to take treatment and in two weeks from the time she was bled she was in her right mind, and her health recovered so far that she resumed her usual household duties. She never had another attack of insanity.

In 1876 I was called to treat a woman for insanity. She was 32 years of age and the mother of four children and had always had good health. She was violent and the sight of her husband invariably threw her into a rage. Obtaining her confidence I secured her permission to bleed her. I bled her nearly to fainting and she became calm. I then gave her a brisk mercurial cathartic and kept her under the influence of nerve sedatives. In three weeks' time she was well and has remained so since.

In 1876 I was called to see a woman 20 years of age who had been confined two months previously and had a continuous uterine hemorrhage ever since. The hemorrhage was not excessive but sufficient to keep her in bed most of the time. She was anemic. Specular examination showed the parts in normal positions and the flow to be intra-uterine, with no indications of intra-uterine tumors. I therefore concluded that there was a constitutional tendency to hemorrhage. I concluded to bleed from the arm with the idea of stopping the intra-uterine flow by a revulsive effect. I drew from the arm about a half pint of blood, when symptoms of fainting appeared. I then stopped the flow and put the woman to bed and ordered her to keep quiet and in a horizontal position. The uterine hemorrhage ceased and the next day I ordered a tonic of iron and cinchona. She speedily recovered and had no further uterine hemorrhage.

In 1894 I was called in consultation with two other physicians to see a man 56 years of age, weighing 225 pounds, who had been for two days in a state of complete paralysis, unable to move and in a profound stupor. I advised blood-letting but his physicians had never bled any one and requested me to do it. I opened the basilic vein and took between three and four pints of blood from him. In an hour afterward he opened his eyes and made some movements with his left arm and leg. He was able to swallow some fluid. I advised that he be bled the next day to a like amount; this was done and convalescence was without backset. This man fully recovered his usual health so that he is able to attend to his duties as a farmer.

In 1895 I was called in consultation with three other physicians to see a woman 30 years of age, who had been having violent spasms of eclampsia for six hours. She was nearing her full term in pregnancy. The spasms came on intermittently, occurring with every pain, the patient being in stupor between spasms and unconscious all the time. Digital examination showed no dilation. I advised bleeding, and this was done to the extent of over two pints. The spasms soon almost entirely ceased, and in three or four hours dilation took place, and three hours later she was delivered of a dead child near full term. The woman made a slow recovery but is now well.

I could augment these reports considerably if there were necessity for it. My desire is to call your attention anew to this almost out-of-date method of meeting cases of emergency, and to urge physicians to equip themselves with the proper knowledge and instruments for resorting to this expedient in cases of sudden congestion of the vital organs, believing that such positive good results can be obtained by no other therapeutic agent, particularly in desperate cases. I have had uniformally good results from this treatment in puerperal fevers, eclampsia, paralysis from congestion of the brain, brain fever, meningitis and cerebrospinal meningitis, pneumonitis in its first stages, congestion of the lungs, liver and abdominal viscera, peritonitis, croup, tonsillitis, hemorrhage of the lungs and incipient phthisis. Repeated bleedings will do more to cure consumption in its early stages than any other single agent, especially when used in conjunction with an open air life and in a dry and medium high atmosphere. I do not wish to be understood as advocating blood-letting indiscriminately, but want to call attention to its value in cases where indicated, and where in my hands it has proved to be invaluable. I would have every medical student instructed in the art of venesection in all its forms and its therapeutic value and use. Blood-letting is today almost a lost art, not because of its ineffectiveness, but because in times past it came to be the great remedy of quacks and charlatans, and by abuse lost favor with physicians. The assertion that because "blood gives life, you jeopardize life when you withdraw blood," is not true even in normal conditions; but in these emergencies it is neither true in theory, practice nor fact; and the operation of venesection is perfectly legitimate and imperative when necessary to relieve suffering or to save life.

A PLEA FOR A UNIFORM DIASTASE TEST.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa, June 1-4, 1897.

BY C. C. FITE, M.D.
NEW YORK.

Considering the great importance of diastase as a therapeutic agent, it is certainly to be regretted that, up to this time, no uniform test has been agreed on for determining its starch-converting power. My purpose in presenting this subject before the Section is to ask your attention to this fact, and to suggest that a committee be appointed to present the matter before the United States Pharmacopeia Revision Committee, with the hope that the next edition of this work will contain a test which can be adopted as a standard and prevent the confusion now existing. It is a great misfortune that we have no uniform diastase test, and we should urge upon the committee that all of the tests now used by various chemists and manufacturers of diastasic products be carefully examined into and the best test adopted as a standard.

One of the complications due to there not being a standard test is that various manufacturers of diastasic products are constantly misconstruing, and therefore naturally, in the heat of business competition, misrepresenting the claims made by another, working along different lines, using different tests, reaching different conclusions, and representatives of such houses receiving instructions which they do not always fully comprehend, not always being chemists themselves; the medical practitioner has to listen to various statements as to the converting power of various products, while these contradictions only serve to destroy his faith in chemists, and weaken his confidence perhaps in all parties concerned, and his proper appreciation of diastase as a therapeutic agent is destroyed; and this does a great deal of harm without good results to anyone. A standard test would settle all this, and I am sure that no reputable manufacturing chemist would object to such a test being adopted, but would cheerfully accept one which met the approval of the Revision Committee of the United States Pharmacopeia.

The true scientific spirit is to arrive at the truth, and it is to be regretted that some presumably reputable manufacturing houses constantly mislead the profession by sending out literature claiming that their products contain diastase when they do not, and in other cases intentionally misleading their readers as to the amount of diastasic power. As long as we have no standard test, it is impossible to prevent fraud of this kind, because so long as there is no standard test, different methods of testing will lead to different findings, and no definite and accurate conclusions can be reached.

Any one taking up the study of this matter will find one chemist talking about 257 degrees of diastasic power, another will refer to 3 per cent. value, another will give a ten minute test, another thirty minutes, while others will not mention any time at all. Some years ago I had occasion to approach, or I should say reproach, a manufacturer for claiming diastase in his liquid malt extract, for I told him that I could find none in it. He asked me how long I let the starch remain in the solution? I replied, "Thirty minutes." He asked me to call at his office the following day, which I did, and he showed me a sample of partially digested starch. I asked him how long he allowed the starch to remain at the temperature of 100 degrees with the liquid malt extract, and he replied with a smile, "Eighteen hours."

One of the difficulties in establishing a standard test which would meet all requirements, and not unduly prejudice the prescriber against any given semi-solid or dry malt extract containing diastase, would be that such preparations have a certain food value, and are used also as vehicles for various medicaments. Therefore, it would be unfair, and practically impossible, to isolate the diastase contained in them so as to make a comparison with an isolated diastase, such as the one known as taka-diastase. It would therefore appear to me that the only way to solve the problem would be to have a test which would show how many times its weight a given product containing diastase would convert of starch in a given time. The prescriber could then readily estimate what dose he would administer of one of these preparations, by keeping in mind the amount of converting power represented by such a product, whether it was the malt extract plain or one of those used as a vehicle for any given medicament. This makes it more complicated to establish a satisfactory test for diastase than it would for pepsin.

Some recently exploited dry forms of malt containing diastase appear to have some power in liquefying starch, but only to a certain extent, and not by any means completing the process in the manner we should reasonably expect. All difficulties of this kind, not losing sight of some of the liquid malt extracts which are supposed to have diastatic properties—but have not—could be cleared up, if there was a standard official test, and producers of preparations could not then as readily make false claims and hide themselves behind some supposed test with a long name to it, that nobody else ever heard of or ever knew anything about.

I have had occasion to confer with quite a number of chemists on this subject, and the difference of opinion found is simply astonishing, while it is not to be wondered at that medical practitioners have grown to be somewhat tired of the whole subject.

One of the difficulties to be met with in arriving at a proper solution of this question, is that some chemists use a test the purpose of which is to determine how much maltose is formed in a given time, whereas others merely watch for the period when free starch disappears. From a therapeutic standpoint, our desire should be to so supplement the ptyalin with diastase that we could confidently expect the proper conversion of starchy food into assimilable products, such as maltose and the various dextrines, so that the duodenal secretions would, without undue effort, finish the process. I would therefore say that a thirty minutes test, and the disappearance of the free starch within the thirty minutes, in a neutral medium at 100 degrees F., should form the basis of a reasonable test from the practitioner's standpoint; and surely diastase is produced for the physician's prescriptions and not for the chemist's amusement.

It is well established that the ptyalin of the saliva ordinarily acts for at least thirty minutes after the close of an ordinary meal, as the stomach contents does not generally reach the degree of acidity necessary to impair or destroy diastasic action before that time. It is therefore evident that, as diastase is administered therapeutically during or immediately after a meal, a thirty minute test would be of more value to the medical practitioner than any other, and would enable him to judge more correctly as to what dose of diastase he should administer to a given patient, and as to whether he should administer an alkali before the meal is taken.

A standard test should not only specify the exact degree of conversion of the starch, the temperature, the number of minutes, but should also designate what variety of starch is to be used, as it is well known that no two varieties of starch are acted upon by diastase in the same way. Bermuda arrow-root starch is uniform and readily obtainable, and would be the most desirable, as various brands of corn starch and potato starch differ very greatly in reaction and physical structure.

It was formerly believed that albuminous foods must be completely converted into true peptones before they could be absorbed, whereas it is now generally conceded that the liquefaction and the production of albumoses is really the essential step in peptic digestion, and I feel sure that we can assert with confidence that if we liquefy cooked starch and produce a reasonable amount of maltose, the rest of the starch being converted into the various dextrins as above stated, we have secured all the therapeutic results desired from the administration of diastase. This is why I would insist on the test showing the point at which free starch disappeared, and not the complete conversion of the starch into maltose.

As I have been engaged a considerable portion of my time during the last six years in studying and handling various diastasic preparations, I feel that I am in a position to present this subject from a practical standpoint, for I have found that my labors have been doubled by the confusion now existing in regard to the various methods of testing such products.

The pharmaceutic chemist should bear in mind always that the ultimate purpose of his work is to produce satisfactory preparations containing definite properties, and to get rid of all unnecessary technicalities and chemic circumlocutions, so as to make the qualities and purport of any preparation he may exploit perfectly clear to the medical practitioner, without any undue labor and investigation being expected on the part of the latter. It is just this careful work, on the part of the pharmaceutic chemists, that has produced such great strides in the development of and the purification and concentration of medicaments formerly handled in a crude and uncertain way. The wide-awake and conscientious practitioner fully appreciates this fact, and is always ready to give due credit for any accomplishment in this direction that enables him to the more readily relieve his patients of their ailments without offending their esthetic sense, and the gradual elimination of the cruder forms of drugs has at this time reached a remarkable degree of refinement. It is surely a long step from an enormous dose of powdered Peruvian bark to a gelatin capsule of quinin, and even within a few years great progress has been made from the original nauseous and bulky pepsins, of only strength enough to digest a few grains of albumin, to the high power pepsins now produced without any special effort.

Another problem which should receive very careful attention is whether or not pancreatic extracts should be standardized by the same tests as vegetable diastase. I am convinced that, while we may get good results in certain cases from the use of pancreatic extracts, we can not depend on a definite diastasic action which is or should be similar to that of ptyalin, for we must remember that nature places the amylopsin of the pancreatic juice and the other various duodenal enzymes below the stomach, and they are intended more for completing and finishing the changes already begun by ptyalin before the peptic digestion supervenes. In other words, they are not intended by nature for beginning the conversion in the stomach, but act, we might say, on the food mass later, when it has an acid reaction, during the time it is being changed from an acid to an alkaline reaction, instead of on the alkaline or neutral mass when it is being changed into an acid condition, as is the function of the ptyalin, and therefore we should consider vegetable diastase supplementary to ptyalin, acting on the starch preliminarily and not secondarily.[1]

Should we not go still further and ask that a definition be made as to what constitutes a malt extract, so as to be able to make the proper distinction between the semi-solid malt extracts and their attenuations, which contain diastase, and the liquid malt extracts, so-called, which do not?[2]

102 West 93d Street.

DISCUSSION.

Dr. E. T. **Stewart** of Detroit—As this paper brings up a question of much importance, and brings before us the results of an extended investigation, I move that a committee be appointed, consisting of the Chairman of our Section and two other members, to suggest a practical test for diastase and to recommend the same to the Committee on Revision of the United States Pharmacopeia, and that the result of their deliberations be transmitted to the American Pharmaceutical Association for its concurrence. I have myself given considerable attention to the subject, and as a result of about three thousand tests made under my direction by Prof. C. C. Sherrard, a competent chemist, I may report that we found a great variety of methods in use and corresponding differences in the results. Active diastase has great starch-transforming power; for instance, a few grains are sufficient to convert all the starch taken in an ordinary meal by an adult in the period of less than a minute of time. Many of the preparations said to contain diastase have no starch-digesting power whatever. Everything depends, therefore, on the quality of the diastase, and some regulation is urgently needed so as to enable the physician to differentiate between the true diastase preparations and those which are falsely alleged to contain diastase.

Dr. F. R. **Stoddard** of Shelburne, Vt.—I am impressed with the importance of the positive determination of the digestive power of diastase and preparations which claim to have diastasic power, and of the necessity of the establishment of some uniform test by authority of the pharmacopeia. This is a question which should interest every physician who prescribes these remedies. The manufacturer, under present conditions, sends out these preparations, and the physician uses them, expecting them to fulfil the claims of the manufacturer and do a certain amount of work in the digestion of starchy foods, but at present he has no means of knowing whether these claims are true or false. I therefore heartily second the proposition that a committee be appointed to report on the feasibility of the adoption of a uniform test for diastase.

Dr. W. B. **Hill** of Milwaukee, Wis.—This is a question of great importance. It is a subject which should engage our attention as physicians who prescribe these preparations; and we should have better knowledge of their digestive or diastasic value. We need it especially, because the American people suffer from what may be called amylolytic indigestion, owing to a number of contributing causes. In the first place, there is so much starch in our food; and in the second, owing to hasty deglutition, there is a deficiency of ptyalin. There is, therefore, a great demand for diastase and preparations which assist in the digestion of starchy foods, and there is no doubt that some form of diastase will be introduced in the next pharmacopeia, and a higher test should be established and a standard be made before its introduction. It is well for us to take it up and give it due consideration at the present time, so that we may offer some well matured suggestions to the Committee on Revision, either at this or our next meeting.

Dr. F. **Woodbury** of Philadelphia—The chemistry of the digestive processes is now so well understood by physicians that the form of dyspepsia characterized by deficient amylolytic power in the secretions is now generally recognized. As a result, physicians no longer prescribe pepsin for all conditions of imperfect digestion, but they differentiate the cases in which a starch-transforming ferment will afford the desired relief from those in which the proteid digestion is at fault. Therefore, measures to promote the secretion of saliva, and of the pancreatic and intestinal juices, are recommended, and there is a constantly increasing demand by the profession for starch transforming ferments. It is most important, therefore, that some uniform test should be formulated by the biologic chemists, which may enable us to distinguish between the physiologically active and the inert, or fraudulent, diastasic preparations offered to us by the manufacturers.

Dr. R. **Harcourt Anderson** of New York—I would ask Dr. Fite as to the effect of increased secretion of gastric juice upon the action of diastase. Does hypersecretion and increased acidity retard or prevent the action upon starch? If so, what measures may be adopted to overcome this difficulty?

Dr. **Fite**—In reply to Dr. Anderson, I would say that an increase in the acidity of the gastric juice will retard the action of diastase in the stomach. In cases of hyperacidity, it is necessary to administer an alkali before the meal, and then by the use of diastase taken with the food, we can overcome this difficulty and relieve the symptoms. The reason why so many physicians have failed to relieve patients suffering from starchy indigestion is owing to the existence of this condition of hyperacidity and their neglect to administer the alkali before meals. It is, however, true that a moderate degree of acidity does not inhibit the action of diastase. Bicarbonate of sodium, in ten to twenty grain doses immediately *before* each meal, will be of great assistance to the action of the diastase taken *during* the meal.

Six years ago, when I first took up the study of this subject, diastase was practically unknown to a majority of practitioners, whereas now it is used to a great extent by physicians all over the world. The loss of saliva by tobacco-chewers, the defective mastication of food and the limited secretion in young children, with the great proportion of starch in our food, as pointed out by our Chairman, contribute to make diastase and its preparations prominent in therapeutics, and there should be some method of standardizing these products, or of ascertaining the real value of diastase by some practical and convenient test by authority, so that there should be some uniformity on the subject.

The Chairman, Dr. Hill, put the motion, which was adopted unanimously, and appointed to serve on the committee with him Dr. Fite of New York and Dr. Stewart of Detroit.

IMPROVED METHOD OF COCAIN ANESTHESIA.

A REPLY TO A KINDLY CRITICISM OF THE AUTHOR'S METHOD OF ANESTHESIA, BY J. F. OAKS, PH.C., M.D., PUBLISHED IN THE JOURNAL OF JULY 17, 1897.

BY P. L. ANDERSON, M.D.
CHICAGO, ILL.

The object of the new method is to avoid toxic effects, allay fears of patient, saving of time and cocain to both patient and surgeon, and incidentally to bring before the profession the fact that, in the prone position, patients recover from toxic effects cocain, and that if patient is cocainized in the prone position, and operated upon in the same position, there will be no toxic effects of the drug so long as that position is maintained. With this brief statement of facts from the original article I will reply to the Doctor's criticisms in the same order as he presents them.

---

[1] Medical News, Feb. 6, 1897, p. 167.

[2] Boston Medical and Surgical Journal, Dec. 31, 1896, p. 669; Albany Medical Annals, March, 1895.

The preliminary use of the one-tenth per cent. cocain spray solution is no essential factor in the ultimate anesthesia of the nasal mucosa; its purpose is merely to allay the hypersensitiveness of the mucous membrane preceding the application of the 25 per cent. cocain solution on a cotton wrapped probe. It is simply a nice, pleasant way of introducing a very disagreeable subject. To touch or rub the nasal mucosa with any foreign substance without some previous spraying of a weak solution of cocain causes a disagreeable tickling sensation, more or less pain, while a certain amount of fear takes possession of the patient's mind, which keeps him on the *qui vive* until the operation is completed. He is constantly expecting more trouble because he was hurt at the preliminary step of the operation. I use the Davidson spray tubes, and with the improved instantaneous cut-off, made by a firm in Port Huron, Mich., there is not the slightest trouble in controlling the amount of one-tenth per cent. solution to be used as an initial step. As to the strength of the solution of cocain used (25 per cent.), to be candid with the gentleman who so kindly criticises my article, I privately whisper to him (of course I would not say it to anyone else) that I have for two years used a 50 per cent. solution; but in writing for publication I think it poor policy to advocate such strong solutions to others, who might misunderstand my meaning or who, through carelessness or inexperience, might do much harm with such strength of solutions. Idiosyncrasies are so decided, sudden and rare that the difference between a 5 per cent. solution with tampon and 25 per cent. solution new method amounts to little or nothing, for as serious results have been reported from the use of 2 per cent., as well as 5 or 10 per cent. The demonstrated clinical fact is that less cocain is absorbed into the general system by this criticised method than is done by the weak solutions with the tampon method, theories to the contrary notwithstanding. In relation to the time required in ordinary cocain anesthesia I beg to refer to no less authority than Professor Ingals of Chicago. Dr. Ingals, in speaking of cocain anesthesia in Gould's year book of treatment for 1897 says: "For intranasal operations ten to twenty minutes or more is required for cocain anesthesia."

It might be of interest to learn that since the publication of the original paper, the author has in several test cases succeeded in producing complete anesthesia for acid or galvano-cautery in one and one-half minutes, using a 50 per cent. solution of cocain. The shorter the time required for anesthesia, the less is the toxic effect. In comparing the tampon method with the author's method, Dr. Oaks forgets that the tampon, in order to retain its position in the nose, necessarily presses just as much against the septum as it does against the turbinated body, which produces the absorption of double the amount of cocain required. Again, acid and galvanic cauteries cover but small spaces, sometimes a mere dot no larger than the letter O in the title of this article; often it is but a line, one-eighth to one-sixteenth of an inch in width, and from a half to an inch or more in length. It is not logical to contend or theorize that a tampon one-half to one inch or more in length and one-fourth to half an inch in width, in close contact with two or more parts of the nasal cavity, and remaining there for fifteen to twenty minutes, will produce less toxic effects than the application of a 25 per cent. cocain solution on a probe wrapped with just sufficient cotton to cover its metallic end, which can be accurately applied to only those parts to be gone over by the cautery. From my early experience in the use of the tampon method and 5 per cent. cocain, I observed that my patients speedily recovered from the toxic effects of the cocain by assuming the prone position. After the unpleasant occurrence of fainting during some six or seven septum operations, I have for the last few years anesthetized and operated for spurs, ledges and deflections of the septum with the patient in the prone position, and not once have I had the occurrence of the toxic effects of cocain, nor a case of hemorrhage that was not easily controlled in from one to three minutes by the use of hydrogen peroxid. The use of this drug as a hemostatic in intranasal operations was first brought to the notice of the profession by the author in an article on "Abnormalities of the Nasal Septum (*New York Medical Journal*, Feb. 23, 1895). Clinical facts must always speak stronger than mere argument or theories. While the improved method of cocain anesthesia is new to the medical profession, it has been in constant use in the author's practice for the last two years, during which time I have treated 2,114 cases and operated on 1,163 for intranasal disease. The method of anesthesia and the prone position of operations is not a fancied theory to be torn to pieces by mere argument; it is a solid, substantial clinical fact based on actual work done by the author, and capable of verification by records of cases and by Drs. Stuart Johnson, F. A. Leusman, G. H. McFatrich, T. Wilson Deachman, W. H. Weaver, Carl von Klein and many others who have on many occasions witnessed the anesthesia and operations of the author.

A STUDY OF THE CAUSE AND EFFECT OF URIC ACID IN DISEASE, WITH SPECIAL REFERENCE TO ALKALINE DRINKING WATER.

BY W. W. REED, M.D.
FOWLER, COLO.

I have been incited to an investigation of this subject by the great frequency with which I have met with cases of various manifestations of uric acid in the Arkansas valley, where the drinking water is almost universally impregnated with alkali, and where the people partake largely of a meat diet.

Since reading Professor Haig's little book, "Uric Acid in the Causation of Disease," I have become extremely interested in the subject, and find in it a wide field for study and investigation.

That the alkali water is in some way accountable for so many cases, I am fully persuaded, but in so far as I have ransacked the authorities and the literature on the subject, I have failed to find any satisfactory explanation of the phenomenon. In this paper I do not presume to advance anything new, but only offer a few facts gleaned from a study of my own cases and from a careful review of my library, on the subject. Some points have been entered into rather minutely, and many well known physiologic facts reviewed, but this will be excused on account of the importance of the subject.

Of the seventy elementary substances known to chemists, only sixteen are found by chemic analysis to enter into the composition of the human body, and these, aside from oxygen, hydrogen and nitrogen, are not found free, but in compounds which go to make up the various tissues and the blood. These compounds naturally divide themselves into organic and inorganic

The most important of the organic compounds are: 1, water, forming two-thirds of the entire weight of the whole body; 2, common salt, found in all the tissues; 3, phosphate of lime, largely entering into the structure of the bones and teeth; 4, potassium chlorid, which exists in the blood, nerves and muscles.

The organic compounds are subdivided into nitrogenous and non-nitrogenous, the former represented by the proteids, the latter by the carbohydrates and fats.

Hence, to enable an active, living human organism, constantly undergoing a loss of substance by the mechanical force exerted and the heat given off, to provide material to exert this force and repair worn out tissue, is the chief function of the food we consume.

The food must contain compounds of proteids, fats and carbohydrates, with water, that every constituent part of the body may be supplied with the necessary material for the performance of its function. In the digestion of these compounds a certain proportion of useless and indigestible material leaves the body in the form of water, carbon dioxid, urea, and certain unimportant saline compounds. The chemic composition of these compounds before entering the body as foods can be very accurately determined, as can the excretions; but the physiologic chemist is still puzzled over some of the intermediate chemic changes taking place during assimilation and absorption within the body. However, it is well known that in the vital processes, and metabolic activity, the fats and carbohydrates are broken down into simpler substances, and their unused carbon, combined in part with oxygen, is passed out of the lungs as carbon dioxid, while their hydrogen, combined with oxygen, passes out as water.

We are now interested more particularly in the study of proteid oxidation, its suboxidation, and its relation to the formation of the nitrogenous wastes, viz., urea and uric acid. Proteid oxidation differs from the oxidation of the fats and carbohydrates, in that some of its liberated carbon not only combines with oxygen to form carbon dioxid, while its hydrogen combines with oxygen to form water, but also some incompletely oxidized carbon and hydrogen remain, and combines with nitrogen and oxygen to form urea, which represents the chief nitrogenous waste.

In the processes of assimilation and nutrition, every healthy cell in the body not only takes from the food the material required for its immediate use, but lays by some little excess. In addition to this functional economy on the part of the cells, we find special food reserves or reservoirs within the body, from which the tissues can draw food substance. The oxygen reserve is found largely in the blood, and special storage of oxygen is rendered unnecessary, as it can be drawn from the air at any time. The two great storehouses of the body are: 1, the liver for the carbohydrates; 2, the adipose tissues for the fats. These supplies are drawn upon in the intervals between meals and during starvation.

As the proteids probably are but little concerned in energy production, and are only required to renew proteid waste in the tissues, nature has provided no storehouse for their excess. Proteids are not only oxidized after being organized into the tissues, but if taken in excess are oxidized without being converted into the tissues. Hence, to get rid of this excessive nitrogenous waste, which is brought to the kidneys in the form of the incompletely oxidized substance, urea, with its concomitant uric acid, is much more laborious to the system than to get rid of the carbon dioxid and water which are formed by the oxidation of the carbohydrates and fats. Here, as I take it, we have a key to the situation in the treatment of the uric acid diathesis: *i. e.*, to cut off proteids from the diet.

Accepting it then, as a demonstrated fact, that the progenitors of urea excreted from the body, are the proteids taken as food, and that urea itself represents the ultimate product of nitrogenous oxidation of the food and of the destructive metabolism in the tissues, the question naturally arises as to what intermediate steps are taken before the urea is excreted in the urine; and whether urea is finally formed in the kidneys, or merely separated by them from the blood.

A great deal of theorizing has been indulged in, regarding the antecedents and place of formation of urea, and the ideas and investigations of able men do not yet harmonize on these points. Murchison believed urea to be formed by the liver, and his views, until recently, were more widely accepted than those of any other writer. Garrod still holds, that the kidneys not only are concerned in its excretion, but also have to do with its formation. Cantoni, whose teaching the German and American writers accept, regards the living tissues as its direct source. Ebstein thinks it is formed, chiefly, in the muscles and bones. Thus it will be seen that our physiologic knowledge is such, that we are not in a position to draw safe conclusions even yet on these questions, but notwithstanding this diversity of opinion, certain facts that may guide us in our meager investigations, have crystallized out of this chaos.

We learn that the muscles contain by far the most proteids of any tissue in the body, and so naturally look to them for a solution as to the origin or source of urea.

Clinical analysis shows that they contain no urea proper, but that they always contain kreatin, which is a substance known to be directly intermediate between proteid and urea.

Kreatin is also found in the brain and nervous system, in the spleen, and in many glands. Since it belongs to a group of nitrogenous compounds, which the body is unable to utilize for reconstruction into proteid, but must be gotten rid of, it seems quite probable that it is the first step in the chemic decomposition of the proteid tissues, toward urea. Kreatin is soluble, and readily dializable, and therefore fitted to pass rapidly into the blood stream. The blood always contains urea, but it is doubtful just where the kreatin is changed into urea. On the whole, the evidence seems to show, and it seems to be very generally conceded too, that it is only separated from the blood by the kidneys, and is not produced by them. Blood from the renal artery contains more urea than blood from the renal vein. which would not be the case, did the kidneys produce the urea. Moreover, we can find no sign of any special activity of any group of tissues, either in the liver or kidneys, such as one would expect to find, if the urea always came from the breaking down of formed-tissue cells. In suppression of urine it is also found, that urea accumulates in the blood, which would not be the case. unless it was normally formed elsewhere, and carried off by the kidneys

Urea itself, is, as we have seen, normally found, both in the blood and the urine, and may vary widely in amount, depending upon the food and the metabolic activity, within a physiologic limit.

By virtue of the fact that it is a neutral substance, unirritating and readily soluble, it is constantly drained off by the kidneys, but not so with its copartner in human misery, uric acid.

Uric acid being much more insoluble, and forming many insoluble salts, and also owing to its irritant action on the vasomotor system, is extremely liable to be retained, and may become a potent pathologic factor in the causation of many diseases, where faulty elimination occurs. Like urea it is a product due to deficient nitrogenous oxidation, and also has an imperfectly understood pathology. Garrod and Liebig suppose that uric acid is an early stage in the transformation of urea. Hoffman believes, that it is formed from the decomposition of the urates, and Haig, whose ideas and investigations have recently revolutionized the whole subject. teaches that uric acid and urea have the same antecedents but that uric acid is not formed from urea, but concomitantly. In his experiments he has shown that it is formed in the system in the constant and direct ratio, of 1 to 33, *i.e.*, for every 33 grains of urea 1 grain of uric acid punctually forms.

Before entering into the consideration of the elimination of urea and uric acid, let us recall for a moment the minute anatomy and physiology of the kidney structure. It is made up of peculiarly arranged tufts, of very small arteries called glomeruli; these are enclosed in the finely constructed cellular capsule of owman, and this capsule is held in a fibrous enve- or capsule of Malpighi, the continuation of which tes the contorted uriniferous tubule. Into the mit of each capsule of Malpighi, one of the ulti- branches of the renal artery enters (the afferent l) and breaking up into a capillary network, forms the glomerulus. The blood is carried away from this glomerulus, by a small vein (the efferent vessel), which does not at once join other veins, but breaks up into a capillary network, which surrounds the adjacent uriniferous tubule. By means of this mechanism, a thin stream of blood constantly flows through the glomeruli, only separated from the excreting tublule by a very delicate membrane—the wall of the capillary vessel. The Malpighian capsule has been regarded as a funnel, and the membranous walls of the glomeruli as very delicate filtering paper, into which the blood is poured. The mechanism of the renal secretion, is then seen to consist of two distinct parts.

1. The glomeruli through which the filtration of water—dehydration of the blood—takes place.
2. The active secretory apparatus, consisting of the secreting cells of the capsule of Bowman, and those of the uriniferous tubules, which have to do with the removal of urea. Normally the organ is abundantly able to perform both the functions properly.

The blood which supplies the kidneys, is brought directly from the aorta, by the renal arteries, so that it has but recently left the heart. The venous blood propelled to the lungs is there purified of its carbonaceous waste, but the nitrogenous waste remains, so that the arterial blood in the aorta is pure, only as regards carbonaceous waste, but impure as regards nitrogenous waste. In the normal condition, the walls of the minute renal arteries and veins are relaxed, and the passage of blood is very free, with a profuse urinary flow, while but little of the nitrogenous waste is allowed to re-enter the blood current. Hence, strictly speaking, the blood that leaves the kidneys, is the purest blood in the body, but not infrequently, certain pathologic conditions arise, whereby the opposite obtains, and the urinary flow becomes scanty while the secreting cells of the kidneys fail to remove from the blood, a part of the nitrogenous waste, and it re-enters the blood stream, and becomes a pathologic factor as a result of this faulty elimination. Professor Haig believes, that where the physiologic oversteps the line, and becomes pathologic, there is a defective elimination by the kidneys, rather than an excessive formation of the uric acid, and by numerous and accurate tests he has demonstrated, that its elimination is regulated by the degree of alkalescence of the blood. That is to say, that under normal alkalescence, the uric acid is conveyed to the kidneys, in a state of solution, and eliminated as fast as formed; but in conditions where the alkalescence of the blood is diminished, uric acid and its salts are not so readily held in solution, being very insoluble, and demanding a highly alkaline medium to effect complete solution. Hence, imperfect elimination must follow a lowered alkalescence, allowing an accumulation in the blood. The degree of alkalinity of the kidney structure probably determines, to some extent, how much shall be excreted, and how much retained?

That Professor Haig's views of the pathology are true in the main, I would not presume to question, but under certain environments, with a heavy nitrogenous diet and a continuous ingestion of an alkaline drinking fluid, as is the case with my *clientèle*, it seems quite probable (from my own observation) that an excessive formation also enters largely into the pathogenesis. As the alkalescence of the blood is liable to fluctuation, from so many causes we may have uric acid retention in varying degrees, in which case it may be again carried back into the circulation, and from the blood be precipitated into the fibrous tissues, joints or muscle sheaths, giving rise to rheumatism or gout; or by its irritant action on the vasomotor system of nerves which control the caliber of the blood vessels while circulating in the blood, a rise of arterial tension with a contraction of the arterioles, may occur. Among others, the arterioles in the Malphighian tufts contract, and the urinary excretion is thus greatly decreased. This state of affairs soon brings about a condition of general toxemia, which may give rise to various neuroses. The nerve centers being most susceptible to the irritant action, are the first to feel the deleterious effects of the toxic state, and those organs that are constantly under nerve control in their function, manifest the earliest symptoms. It is now almost universally believed that migraine, epilepsy and chorea are due to this effect of uric acid on arterial tension. In fact all diseases of uric acid origin except gout and rheumatism, are consigned to this category.

We have then two prominent factors in the creation of uric acid diseases.

1. An excess of uric acid in the blood acting as an irritant.

2. An increase in blood pressure from vasomotor spasm, producing a strain on the heart, and causing a hyperemic engorgement of the blood vessels, in the brain, liver, kidneys, etc. As a matter of fact, this process may not stop with simply an hyperemia, but inflammatory changes in these organs not infrequently result. In this relation, it is lately being assumed, by good authority, that albuminuria and glycosuria owe their pathology to this effect of uric acid. That endocarditis, pericarditis, endarteritis, pleuritis, etc., are of uric acid origin has long been an accepted fact.

Now assuming the correctness of Professor Haig's conclusions (and all late practical experience admits that they are true), and using his data, at first glance it seems rather paradoxical, that alkali water could give rise to uric acid diseases. Nevertheless, I have been forced by tracing its origin in so many cases to the firm belief that this is the case. As the pathogenesis of uric acid is, as we have seen, still somewhat obscure, I shall not presume to offer an infallible explanation of this phenomenon. Yet I have worked out an explanation, that seems reasonable and to me accords best with Haig's investigations and my own observations. It is briefly this:

That a free consumption of proteid diet and deficient oxidation of the nitrogenous material generally gives rise to an excessive amount of uric acid. This, by its irritant action on the arterioles of the kidneys, bring about an increased arterial tension there, and consequently diminishes the urinary flow. As a result of this all the uric acid is not eliminated. The alkalinity of the blood being kept high by the constant ingestion of alkali in the water, uric acid is not allowed to leave the circulation, and becomes deposited in the tissues, glands, joints, etc., neither can it be completely eliminated because of high arterial tension in the kidneys, etc., but it is carried round and round in a vicious circle that keeps the arterial tension high and is thus productive of the many evil consequences, the most notable being those of the nervous system. The symptomatology of uric acidemia may be so various in its manifestations, and depends so greatly upon the *locus minoris resistentiæ* of the patient, that to enter upon its discussion would protract this paper to an undue length.

Professor Da Costa, in an article in the *Journal of the American Medical Sciences*, 1881, on the "Nervous Symptoms of Lithemia," has graphically pictured the mental condition of these cases when he says:

"There are spells of languor and lassitude which befall the man whose blood is charged with lithic acid, in which all exertion is painful and which strangely contrasts with his usual energy. Then there is depression of spirits, and gloom that may amount to melancholy. But above all is irritability of temper; odors annoy, sounds infuriate; nothing pleases and it requires more than ordinary self-control to prevent explosions of temper. The man is on edge, and the acid blood literally makes an acid temper. Indeed many a man who has the reputation of being a crank is simply a lithemic, who finds it impossible to control his engendered irritability."

Again the irritating influence of uric acidemia, on the temper, and its magical disappearance, and consequent production of gout, as a result of its deposit in the joints, is typically illustrated in Macaulay's description of the Earl of Chatham: "A cloud settled on him, he, a most affectionate father could not bear to hear the voices of his own children. He bought up houses contiguous to his own, that he might not have neighbors to disturb and annoy him with their noise. His appetite was fanciful and capricious, he was melancholy and irritable. The disputes of his colleagues, the responsibility of state bewildered this boldest of men, who behaved at times like a hysterical girl, bursting into a flood of tears. He had passed months without a twinge of the gout to which he had been subject since boyhood. At length the gout returned, his nerves were newly braced, his spirits became buoyant, he was once more the proud resolute statesman."

Again, Haig, in a quotation from *Punch* aptly illustrates the seeming trivial circumstances which the mind of the lithemic will seize upon, as a cause for worry. A middle aged man is represented as reclining in an easy chair, in a luxuriously furnished sitting room and surrounded with all the comforts of life. It is afternoon. On the floor near him is lying his dog, resting with half an eye open. But this man in spite of all his luxury and comforts is not happy, and the cause of his misery is the uncomfortable thought which has gradually forced itself upon him that his dog does not love him. Presently he arouses himself sufficiently to call his dog with the object of putting to the test the cause of his misery, but the animal rushes to him and evinces such evident pleasure and affection that his master is soon compelled to abandon the idea, that his dog does not love him. The man who is thus unable to make himself believe that his dog does not love him is still unhappy and he rushes to the other pole, and begins to worry himself, because he does not love his dog. This is more difficult to disprove and Punch intrudes no further upon him. There is no doubt whatever that these descriptions are drawn from nature for I have seen just such cases and they well illustrate the symptoms of uric acid sufferers, and point out conclusively, that the cause of the misery is central, *i. e.*, the circulation in the brain. The inference is, that in all cases characterized by recurring and persistent headache, irritable temper, aversion to mental or physical exertion, with a scanty urinary secretion, uric acid should be suspected and a careful and systematic analysis of the urine should be made. As we have seen, acids, or any drugs acting as an acid, by causing a lowered alkalinity of the blood, will clear the blood of uric acid, thus relieving headache, lowering arterial tension, etc., but by so doing, the uric acid is drawn into the fibrous tissues and joints, and may precipitate an attack of rheumatism or gout; therefore, where it is desirable to relieve the headache and lower arterial tension, etc., quickly by giving an acid the salicylates should follow in large doses to effect its removal from the system. As a matter of course the proteids must be restricted, to cut off the amount of uric acid introduced into the system.

Animal food, rich soups, strong coffee and tea, should be studiously avoided by all lithemics. To clear out the uric acid after an attack of rheumatism has already developed, the salicylates are indicated.

It is impossible here as in all other diseased conditions to work out a plan of treatment that will fit all cases, as each case differs from the other.

No subject in medicine merits a more careful study today and none offers a wider field for investigation than this problem of uric acid as the causation of disease. Professor Haig goes so far, in speaking of its importance as to say:

"If my premises are good and my deductions sound and if uric acid really influences the circulation, to the extent which I have been led to believe that it does, it follows that uric acid really dominates the function, nutrition and structure of the human body to an extent which has never yet been dreamed of in our philosophy, and in place of affecting the structure of a few comparatively insignificant fibrous tissues, in which it is found after death, it may really direct the development, life, history and final decay and dissolution of every tissue, from the most active glands to the matrix of the nails and the structure of the skin and hair."

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

(*Continued from page 380.*)

Sometimes they were obliged to move the entire hospital, if the location was not safe enough, for the enemy had no respect for them and knew no neutrality. Schmucker with his hospital in Schweidnitz was captured by the Austrians and discharged on parole only after five days. Theden was also taken in 1744 with his whole equipment for the first time, and by the Austrian hussars in the battle of Leuthen, and remained a prisoner the entire winter. He met the same misfortune at the overthrow of Hochkirch, whereupon the king paid him 300 thalers for his loss and gave him free medicines for the following campaign. Again in 1759 he was captured in Poland by the Cossacks and held for several months, being well treated in the meantime. In the next chapter we shall listen to a few German voices which were raised in favor of the neutrality of the hospitals. Very few figures are available on the subject of mortality in hospitals. We will save Bilguer's data for the chapter on gunshot wounds. At one time 15,000 sick and wounded passed through his hospital, of which number about 1,500 died. During the whole campaign this hospital had cost 9,684 thalers, besides nearly sixteen groschen for medicines for each patient.

The prophecy of Frederick the Great, that after his death evil tongues would have their way, found fulfillment in respect to the field-hospitals. A pensioned Prussian general wrote in 1787 concerning the battle of Torgau as follows: "The greatest part of the wounded lost their lives through the intense cold, which was the usual fate among the Prussians where the hospitals were so badly constructed and so ill smelling that every soldier looked upon himself as already dead as soon as he entered one of them. The physicians and surgeons in the hospitals had orders to let all those die who were so wounded that they could not serve again after their recovery, in order to save the cost of their maintenance." Perhaps the general meant to reflect on the admonition of his king who had called to his surgeons: "Do not make me too many cripples," but had taken pains to provide excellent invalid hospitals with the greatest solicitude for the rest of the cripple's life. Of course it can not be denied that in the course of the many wars some abuses had crept into the Prussian system of military sanitation, so that Frederick William II. found sufficient material for reorganization. As before mentioned he placed the system of field-hospitals under a special department of the newly erected chief bureau of war (or war ministry which had not existed under Frederick the Great). Then he improved the station of the military physicians, liberated them from the razor and the broad sword, and a year after the death of Frederick the Great, in 1787, made them a part of the new dispensation in field-hospitals based upon the plans of Dr. Fritze, which left nothing to be wished for in respect to care of the wounded. Out of 100,000 men they estimated about 10,000 sick, and for the whole army in war time allowed four staff physicians and eighteen field-physicians, thirty staff-surgeons, forty over-surgeons and 600 under-surgeons. Besides these there were provided two chief field-apothecaries, four provisors or traveling apothecaries, forty under-apothecaries and ten assistants. The attendants were semi-invalid soldiers who were married, and five of them were allotted to each 100 sick with internal diseases, and ten were allotted to every 100 surgical patients.

A few years later new improvements appeared in Prussia. In 1793 the general staff-surgeon Gorcke called the field hospital into existence, a portable hospital for 1,000 sick and wounded, which according to an order of Frederick William II. was built in six weeks. These portable hospitals were easy to establish and immediately proved their value in the siege of Mainz. Görcke had for a long time entertained the plan of a comprehensive military medical training-school, which was now realized in the year 1795, when the *Chirurgische Pépinière in Berlin* (Surgical Nursery) was founded. It was at first designed to admit and to train a surgical hospital force of fifty men who were not at that time to be lodged with the army.

In 1797 the institution was considerably enlarged, obtained a building of its own and was then to admit company surgeons, to give a better training to those already at hand and to create a good supply of surgeons for the field hospitals. Under the control of a lieutenant-general the general staff-surgeon as director conducted the institution, admitted the students and later gave them appointments; he was represented by a chief staff-surgeon. Of the four staff-surgeons one had oversight of those students who were ordered to the Charité, while the others took their part in the scientific training in the institute. The real governors were the chief-surgeons, eight in number, who attended the students in the colleges and controlled their time, their military apparel and their dinners, which were taken in common, etc. For the most part the earlier students at the Pépinière were promoted, after an examination before the Collegium Medico-Chirurgicum to staff surgeons and regimental surgeons, in about twelve to fourteen years. The number of the students was fixed at eighty-one, aside from an indefinite number of volunteers, who might be foreigners, and that included a number of company surgeons who came to Berlin to study. Before their acceptance the applicants were obliged to agree to serve at least eight years. Every half year nine of them were sent to the army and the same number of new ones taken in. Each one remained in the Pépinière four years and a half: during that time he heard every course twice and received six thalers monthly besides free residence. Besides instruction in the German, Latin, French and Polish languages, in pure and applied mathematics, logic, ethics, history and geography, the professors of the Collegium Medico-Chirurgicum gave theoretic instruction in all the medical sciences. There followed a half year's practical service in each position in the Charité. The Pépinière possessed a library, a collection of anatomic specimens and medicaments, an herbarium, etc. The students were appointed as company and squadron surgeons, and later were promoted either as over-surgeons of the institution or as surgeons of the guard, or regimental surgeons. They could also be appointed as district surgeons or enter the civil service, as they wished. The founding of the Pépinière was for that time, when medicine and surgery were still separated, a progressive step, for both sciences were taught there, but a free scientific spirit could not develop there under the strict discipline. In 1818 it became the Medico-Surgical Frederick-William Institute.

Among the *military surgeons of Frederick the Great*, whom we shall now notice more closely, the great mass were wholly uneducated. Everywhere they were still obliged to appoint barbers' men and barbers' journeymen as army surgeons, who had to shave the soldiers and officers, whose most intimate associates were under-officers and common soldiers, whose most frequent vice was drunkenness. If they indeed found opportunity to listen to their colleagues in Berlin, whose institutions for anatomy and surgery at that time had a great reputation in Germany, yet the regimental surgeons had to bestow an inconceivable amount of labor on their education, which was in accordance with their duty, for all ambition and all school training were lacking. Upon how low a plane of surgical training the army surgeons were, is shown by certain observations noted in 1754 by Muzell, the physician of the Charité. When a pair of scissors penetrated a musketeer's buttock, and excessive bleeding with swelling followed, Muzell advised a dilatation. As the army surgeon could not trust himself to do it, the physician was obliged to do it himself, "probably the severest case he had ever had, and one which required real resolution." Deep in the wound, he found an aneurysm and saved the patient by ligature, not as he supposed of the art. obturatoria but of the art. ischiadica. This ligature is the first made on the last named artery, as I have shown in my work on wounds and aneurysms of the art. glutea. Another regimental surgeon was not in condition to stop an usual flow of blood after the extraction of a tooth, which Muzell accomplished by pressing a sponge into the gap left by the tooth. At one time when gangrene followed an amputation of the forearm, made on account of caries of the hand, Muzell saw the only safety in exarticulation of the humerus, but his salaried surgeon advised against it from fear of the bleeding that it would occasion. Nevertheless it was done. Several days were spent in extracting the bone because they introduced a compressed sponge and let it remain for a long time in order to somewhat separate the head of the upper arm from the shoulder cavity; the patient recovered. This kind of cases, which show clearly the melancholy condition of army surgery, might easily be multiplied. The complaints over their scanty training were so general that Surgeon-General Theden decided to write a book on "Instruction for the Under-surgeons of the Army" (2 vols., 1774). This is said also to have been the guide according to which the master trained his apprentices, since the handbooks of Platner and Ludwig were quite beyond the comprehension of the barbers. Unfortunately in that work the elements of anatomy and physiology were treated so briefly and impracticably that the army surgeon could learn nothing from it. What idea could he get of the frontal bone, for example, when Theden taught him that os frontis had two areas or surfaces, an inner concava (hollow) and an outer convexa (rounded), and various margins or edges, etc. They tormented the students, especially in anatomic studies, quite too much with dry names and figures, which were quickly forgotten again. In 1783 Bilguer published "Directions for Field Surgeons" as everything that had hitherto been written on field-hospitals had been the product of the pens of learned gentlemen who had never participated in a campaign. But when it is seen how minutely and carefully Bilguer treats the subject of gunshot wounds with respect to the direction and shape of the wound and the location of the foreign body, describing the incision in each particular case, it will be understood that the army surgeons worked only from memory and not with talent.

Even at the end of the century, in 1791, Bilguer wrote: "It is well known that on account of the low wages of the under-surgeons in the regiments [the under-surgeons received at that time 4 thaler 3 groschen monthly, and 21 groschen additional from the regiment surgeons, while the Hanoverian squadron or company surgeons received 6 thalers monthly], and the severe military discipline, but few devote themselves to this hard service, and those who do so are usually men who have had no moral training and still less education, and most of them come from the lowest class of society. If the state would see to it that only well-behaved young men with education and a good moral character should devote themselves to surgical science, then the regiments and the provinces might be provided with skilled surgeons and not with privileged murderers; but the state would be obliged to pay these useful and indispensable men better and to respect them more." Richter was right in asserting that a field surgeon who must be told in every particular case how to act, who did not understand how to use his own judgment in applying a general rule to particular cases, was not at all warranted in being a surgeon. If there were any excuse for the ignorance of the under-surgeons it lay in the circumstance that their superiors, the regimental surgeons, frequently knew nothing, although the surgeon-generals often gave daily surgical lectures while in winter quarters. We will not leave the Prussian army surgeon without learning how he looked. For that purpose our poet Schiller shall don the uniform; for the Würtembergers were dressed out in the old Prussian style, which was very stiff and absurd. When Schiller was an army surgeon, in 1780, without the decoration of the sword tassel, having only the rank of sergeant, and with a yearly salary of 216 guilders besides about 36 kreutzers daily, he wore on each side of his face three stiff rolls of plaster of Paris which looked like curls, while a small military hat scarcely covered the crown of his head. A cue hung down his back and a horsehair band encircled the long neck. Felt was worn under the leggins so that the legs, like two cylinders, had a greater diameter than the thighs compressed by tight breeches. As Schiller, in leggins very much spattered with shoe-blacking, could not bend his knees properly, he walked like a stork. In Hanover the squadron or company surgeon in the dragoons had to wear a green, in the infantry a red, and in the artillery a blue uniform.

The leading Prussian war surgeons, at the same time with Richter and Siebold the best surgeons in Germany, were Bilguer, Schmucker and Theden. Yet we must confess with shame that even in these men there was lacking a genuine scientific depth, and many of their works are today scarcely worth reading. The most talented among them was *John Ulrich Bilguer* (1720–1796) of Chur in Graubunden. where his father was guildmaster. After his departure from the gymnasium he studied in the University of Basel and then spent four years in Strassburg, where he lived with the anatomist Vaquin, on whose advice he devoted himself entirely to surgery. Taking his place among the Strassburg surgeons he began to practice, and went to Paris for further training. He was now offered the position of surgeon-major in a cavalry regiment which the Duchess of Wurtemberg was raising. After an examination in Tubingen he began his duties; but in the following year (1742) he went with the regiment, which had been turned over to the king of Prussia, to Berlin, in order to be again examined by Eller and Schaarschmidt, and then be confirmed in his position. Bilguer did not allow himself to lack in courtesy to his French colleagues; originally he wrote his name Bilger, but for their sake he afterward inserted a "u" so that they might pronounce his name properly; but what educated German was at that time without French affectations? In 1744 and 1745 the war took him to Bohemia and Saxony and promoted him to regimental surgeon. After the battles of Kesseldorf, Prague, Rossbach and Leuthen he continually had large hospitals to direct, especially in Dresden and Breslau. When the surgeon-general Boness, successor to Holtzendorff, died, Bilguer received his place. After he had erected the field hospitals in Liegnitz, Jauer and Striegau for the siege of Schweidnitz, he accompanied the army of Prince Henry and later that of the king. After the battle of Kunersdorf, where the supervision was incumbent upon him, he was ordered to Stettin with a large transport of wounded (among them ten generals and over 400 officers). In 1760 he worked in Torgau. He was greatly pleased with the doctor's degree which was conferred on him by the University of Halle (1761) for his dissertation on "The Discussion of the Very Rare Use of, or the Almost Total Avoidance of the Amputation of Human Limbs." This work on amputation, which he wrote in Latin during a four weeks march and amid the greatest disquiet, was published in the same year in German, and within a very short time made Bilguer famous in European surgery.

He was even more famous among the French than the Germans after the celebrated Tissot in 1764 conferred on the book the great honor of translating it into the French. His glory increased when an English and later a Spanish translation followed, based on Tissot's edition, for the proud Briton did not concern himself much with the Germans. The work was one of the few skyrockets which German surgery sent up during the eighteenth century; it flamed all the more brilliantly because Bilguer dared to directly contradict the views of the Académie de Chirurgie, and so caused an enormous sensation. Men like Pott, John Bell, Kirkland, Morand, Martinière, Gesscher. Bertrandi and Schmucker felt moved to subject the maxims laid down by Bilguer to an exhaustive criticism. The author had not imagined that his work would win general applause from the learned physicians and surgeons as "he did not feel himself strong enough to write for the present age" and latter confessed that he had suffered from jealousy and prejudice until Kirkland came to his aid. A year after this publication Bilguer became a member of the Society of Science in Göttingen, of the Roman Royal Academy of Scientists; of the Academy in Erfurt; and a Master of Wittenberg. The winter of 1762 found him in the quarters at Torgau and Leipzig, where he gave daily and free surgical lectures to the surgeons, which formed the groundwork of a new book, "Guide to Surgery in Field-Hospitals" (1763). This work was dedicated to Prince Frederick Henry of Prussia and among other things was enriched with 126 medical and 132 surgical formulæ; this also was translated into French. As Bilguer had served in the hospital with Surgeon-General Theden after the attack on Freiberg, he turned back to Berlin, on the the conclusion of peace, in order to publish his "Surgical Observations" (1763). This contained notes made by him and by various "industrious and observing hospital army surgeons" during the Seven Years' War, and found favor in the eyes of the British. There followed some very thick volumes; "Information for the Public in Regard to Hypochondria" (1767); "Medical, and Surgical Questions in the Injury to the Skull" (1771), suggested by the wound of a superior officer of whom the King had said that only centuries could produce such a man. In this there was chiefly discussed the diagnosis and treatment of concealed fractures, fissures and extravasations. Then appeared "Experiments and Results with Putrid Fever and Dysentery" (1782), and a practical "Guide for Field Surgeons" (1783). Toward the close of his life, 1791, after he had served fifty years, taken part in twelve campaigns, in nine of them as surgeon-general and three as regimental army surgeon, he wrote his last work: "Recollections for Sketches on the Enlargement of Medical and Surgical Knowledge, Together with a Treatise on Cynic Spasm in Case of Wounds." He had earlier been appointed court physician to the Queen and in the year 1794 was enobled. He died two years afterward. Bilguer enjoyed a great reputation and in the translation of his works was a marked exception among German surgeons. Nevertheless, in the best years of his life he possessed so little self-confidence that he asked "some learned, experienced and celebrated physicians" whether his works deserved to be printed or not. His "Restrictions on Amputating" was an eminent scientific achievement, and if he with a too one-sided courage in almost entirely discarding it, shot far over the mark, yet therein lay the starting point of our conservative surgery of today. Bilguer showed here and there an excellent insight, which must, however, be deciphered out of terrible German.

The other surgeon-general *Johann Leberecht Schmucker* (1712–1786), received his first instruction in the collegium medicochirurgicum and from Eller, Buddeus and Senff in the Berlin Charité. Appointed to the tall grenadier guards he was sent to Paris as salaried surgeon for two years, at the expense of King Frederick William I. Here he studied with Petit, Morand, St Yves and especially with le Dran, with whom he became intimate, and to whom he owed most of his surgical knowledge. The first patient whom le Dran turned over to him suffered from stone; he operated for it. and indeed, according to the order of his teacher before a large audience; moreover, he was obliged to maintain the patient at his own expense until his recovery. Le Dran taught his pupil the wise lesson never to follow slavishly in his studies the opinions of individual scholars, and always to hold truth higher than the authority of any man. Schmucker visited the Hôtel Dieu or the Charité daily, where he saw very many operations performed. On his return from Paris he was appointed in 1739 regimental surgeon in the Sydow infantry regiment; in 1749 to the regiment of the guards in Potsdam, and finally, under Frederick the Great, he was made first surgeon-general and director of the surgical field-hospitals. He made eleven campaigns and was active in almost every battle of the Seven Years' War. "A drachm of experience outweighs many pounds of brilliant theories;" according to this principle Schmucker followed his science, and he wished too that in all medical institutions the students at once begin their study in the hospitals, because all theoretic knowledge in advance of practical, however necessary it may be, avails nothing. However, if the causes of certain appearances lay entirely in the dark he would seek to elucidate them by hypothesis, because by means of this so often neglected philosophy, the science of medicine would make very much greater progress. The time was as yet far from ripe for a system. Medicine and surgery were for him closely bound together and of equal value, so that the strife for the precedence of the one or the other seemed to him very ridiculous. While he censured the prejudice, superstition and credulity of his time, he himself still believed in the "mad-worm" of dogs, and recommended the cutting out of a tendon as a preventive of madness.

Schmucker had a large practice, but in his whole life he performed only seven castrations and twelve lithotomies, only one of which proved fatal. When he boasts of having operated gratuitously on poor patients and having maintained them at the same time, and says that he felt richly repaid by their silent gratitude, and the consciousness of having relieved much misery and brought back happiness and joy to a disconsolate family, this information would sound better from the mouth of another than from his own. His fame was wide-spread. Indeed his most celebrated patient was the court physician Zimmermann, who traveled from Hanover to Berlin on the advice of his friend Meckel, especially to be operated on for hernia by Schmucker. Schmucker's best friend and colleague, as he called surgeon-general Theden, assisted him in this operation. To be sure, full of jealousy Theden, when both operator and patient were dead, related that Zimmermann had previously applied to him in Stettin for the operation. Then when Schmucker was to perform the operation and Theden to assist, the latter asked his principal how the operation was to be performed and recommended his vulnerary water, to which Schmucker replied in an unfriendly way. Under dry bandages recovery followed within thirteen weeks after much suffering, which Theden said would have certainly come to pass with his vulnerary water in five or six weeks. Schmucker's greater experience was very gladly conceded by A. G. Richter, who honored him as one of the most skilful and expert surgeons in Germany. He never omitted a dissection in special cases and kept an accurate day-book of all important cases. Since he felt himself unable to carefully observe all the wounded after a great battle he turned his entire attention during one campaign to certain injuries, and with this in view had as many as possible of those having the same kind of injuries laid together. At the siege of Schweidnitz he did this with injuries to the head, and later, in order to test hemlock for cancer, he had thirty sick with scirrhus brought from all the hospitals in Breslau into his hospital. He took no pride in operating quickly; he valued safety more highly. Yet, as a man 70 years of age, he operated with a quick hand and a good eye. After he had performed many difficult operations with success he at times in operations for hernia still feared the criticism of old physicians, who frequently out of jealousy sought to destroy the reputation of their younger colleague.

He upheld warmly the simplifying of instruments. Although in his time much was improved, much that was useless was abolished; the large inconvenient bistouries for the dilation of wounds were made smaller; a scirrhous breast gland was extirpated with a small knife, instead of with an enormous kitchen knife the very sight of which made the patient tremble; the instruments for trepanning and lithotomy were much improved, yet they still kept the great awkward things for amputations. A surgeon who was not especially skilful could scarcely control these frightful amputating knives. Schmucker had them made only five or six inches long but curved like a bow and the handle of the saw was smooth, without any of the ornamentation by which the old saws were rendered so cumberous. He had the entire apparatus for amputating packed so conveniently that it could be easily carried with him in the field. It is difficult to reconcile his usually somewhat exaggerated humane sentiments with the fact that he kept secret the composition of an eye wash, and that "he did not know that a physician could be blamed if he withheld such a remedy, of whose efficacy he had convinced himself by many successful experiments. If the public were more justly disposed toward physicians every upright man would find such a reservation unfair. Meanwhile I have the example of other great physicians before me." Yet the search after novel and strange things which distracted so many, was abhorrent to him; he did not adopt new remedies and methods in the first heat of their discovery, but waited till time proved their merit.

As was usual in that time, his friends first had to persuade him to write; literary fame had no charm for him. He was honest enough as an author to accuse himself of some negligence, since most of his notes were written in the field-hospitals amid the disquiet and hardships of war, and afterward his many duties would not permit him to add any finishing touches. Schmucker was very truthful and tried to report his cases as faithfully and accurately as possible, in the belief that careful and correct observations would retain their value for all time. Therefore he omitted all learned ornamentation, but made the mistake of purposely avoiding every *raisonnement*, in order to leave that entirely to the reader. In his 70th year he feared that his works were written without fervor and charm and was willing to lay down his pen whenever the public should give him the hint. He was already first surgeon-general when he entered on the career of an author with his "Surgical Perceptions" (2 Vols., 1774). The first part contained fifty observations on injuries and diseases of the head. The introduction of cold water applications in wounds of the head secured to him the gratitude [illegible] has made his name immortal.

injuries and diseases of the breast, abdomen and extremities are treated, chiefly gunshot wounds in the lungs, cancer of the breast, radical operation for hernia, hydrocele, lithotomy, amputation. conservative healing of gunshot fractures, etc. From the point of view that progress comes about more quickly through united forces and in order to join the Prussian military physicians together more cordially and to stimulate them to scientific work, Schmucker published some miscellaneous "Surgical Essays" (3 Vols., 1776–1782), into which are collected 135 observations, partly made by himself, partly by regimental surgeons. These, after the manner of their chief, submitted almost entirely bare reports of cases without any epicrisis. He himself published in the collection papers on amputation, the use of the leeches, black cataract, coagulation of milk, hernia. cevadilla seed, etc.

(To be continued.)

SOCIETY PROCEEDINGS.

American Association of Obstetricians and Gynecologists.

Proceedings of the Tenth Annual Meeting, held at Niagara Falls, N. Y., Aug. 17–20, 1897.

First Day—Morning Session.

The Association met at the Cataract House under the presidency of Dr. James F. W. Ross of Toronto.

An Address of Welcome was delivered by Dr. W. R. Campbell of Niagara Falls, which was responded to by the President.

The first paper was read by the Secretary of the Association, Dr. William Warren Potter of Buffalo, entitled

PUERPERAL ECLAMPSIA WITH SPECIAL REFERENCE TO TREATMENT.

The author, at the outset, referred to the views advanced by M. Charpentier at the Geneva Congress last year relative to the treatment of puerperal eclampsia, especially as to the applicability of the induction of premature labor for its relief, and which he said was so at variance with those that he had been accustomed to entertain, and the verity of which he had so frequently tested, that he confessed surprise thereat. It was not in any spirit of controversy that he ventured at this time to oppose M. Charpentier's teachings, but simply in the interest of professional progress and science. The author then gave his own views regarding this subject, saying that they were fortified by an experience and observation extending over a period of many years. Furthermore, in the application of the principles he would lay down and advocate, a measure of success had been obtained at his hands that did not present itself under a contrary method previously pursued. The prinpal object of the paper was to advocate principles which the speaker grouped under the following heads:

1. Though the pathogenesis of eclampsia is unsettled it belongs solely to the pregnant or puerperal state. It is not appoplectic, epileptic or hysteric in character.

2. It depends upon toxemia due to overproduction of toxins and under elimination by the emunctories.

3. These toxins probably have their origin in the ingesta, in intestinal putrefaction, in fetal metabolism, one or all, and there is coexisting sluggishness, impairment or suspension of elimination.

4. When the prodromes of eclampsia appear, the kidney should be interrogated as to its functions and all symptoms carefully watched.

5. Treatment is preventive and curative. Preventive treatment is medicinal and hygienic; curative treatment is medicinal and obstetric.

6. Milk diet and distilled water should be given in the pre-eclamptic state to dilute the poison, hasten its elimination and nourish the patient.

7. Blood letting should only be employed in plethora or cyanosis. It is liable to cause anemia if persisted in or repeated, whereas red blood corpuscles must be conserved, not wasted. Glonoin diminishes vasomotor spasm, hence may be given freely in appropriate cases. Veratrum viride is a cardiac depressant and a dangerous remedy if pushed to an extent that will control convulsions.

8. Eclampsia is the expression of a further maternal intolerance of the fetus; hence as a prime measure the uterus should be speedily emptied of its contents.

9. Medicinal treatment alone is delusive and, when relied on exclusively, is fraught with danger to both mother and fetus; whereas in the prompt induction of labor is found a rational application of science to a desperate condition.

10. Finally, it furnishes, in the present state of our knowledge, the only basis of expectation for a diminished mortality in a toxemic disease of high death rate.

Dr. John M. Duff of Pittsburg opened the discussion and said, relative to the induction of premature labor in cases of eclampsia in which albuminuria is present, that conscientious practitioners would not hesitate, although in exceptional cases careful attention to medicinal treatment would cause the albumin to disappear and the patient would go on to normal labor. As a diuretic, he had secured excellent results from the use of milk, with a spoon, as hot as it could be borne by the patient.

Dr. H. W. Longyear of Detroit was surprised that the essayist did not mention the necessity of inducing premature labor before the occurrence of eclamptic symptoms. Such treatment appeared analogous to snuffing out the light of a fuse after an explosion had occurred. Premature labor should be brought about in every instance in which a daily examination of the urine showed a constantly increasing amount of albumin, with prodromal symptoms of toxemia. During the past year he had induced premature labor twice under these circumstances. In one case the patient was seven and a half months pregnant and in the other eight months. He would not advocate this course merely because albumin was present in the urine, but because of this and the fact that the amount of urea eliminated was constantly decreasing. Hot milk was very valuable, in his opinion, in the treatment of these cases.

Dr. Walter B. Chase of Brooklyn stated that the decrease in the daily amount of urea was a most valuable indication of the probable occurrence of toxemia in these cases. Unfortunately, many eclamptic patients were seen for the first time only when in convulsions, and then the induction of premature labor was the single measure that could be relied on. In certain cases, however, in which the urine clears after a few days, it was unjustifiable to end the period of gestation prematurely. The best method of stopping the convulsions, particularly when arterial pressure is high, is by the administration of veratrum viride.

Dr. W. H. Wenning of Cincinnati doubted the advisability of bringing on premature labor under all circumstances in which toxemic symptoms develop. In many cases, if the os was rigid and not dilated, there was danger of inducing convulsions in the attempt of the obstetrician to dilate. He considers the psychologic element an important one. He gave the history of a patient who presented no symptoms whatever of toxemic infection, there being no albuminuria or edema present, but who died shortly after the birth of her child. Another patient fearing that her child might be born before the expiration of nine months from the date of her marriage was in a state of constant nervousness on this account, and when labor finally took place forceps had to be used. The patient soon developed a condition of marked apathy and would pay no attention to her child. On six different occasions she had a convulsive seizure immediately after the physician's visit and just as he was leaving the house, but each immediately ceased on his being recalled. The patient finally died, although there had been no true symptoms of toxemia.

Dr. Charles Stover of Amsterdam, N. Y., said an important point was, how soon can the condition of puerperal eclampsia be diagnosticated? He emphasized the importance of a daily analysis of the urine. If the physician is called to see a patient late in the progress of the case the uranalysis might present entirely different features from that in the beginning. He knew of three cases which occurred during the past three months in which the attending physician had waited for more marked symptoms to occur after albuminuria had developed, and each of the patients died. He referred to the method of Dr. James H. Etheridge of Chicago of estimating the amount of urea, and considered it a valuable one. He also spoke of a case which came under his own observation, in which but 500 grains of urea were excreted daily when there should have been 1,300, the patient developing eclampsia.

President Ross said that he had found that the occurrence in females during early life, of exanthematous fevers, had a marked influence on subsequent renal insufficiency; and in more than one instance he had been able to trace this insufficiency to an attack of scarlet fever, or diphtheria, occurring during childbirth. The question of puerperal eclampsia was still unsettled; its pathology was shrouded in darkness, and a step forward would be for the larger medical associations to institute a series of investigations with the hope of determining its cause. In many of the worst cases premonitory symptoms were not present at all. He considered it unwise to use haste in emptying the uterus, when this has been determined on, as there was great danger of lacerating the parts. The question as to the advisability of inducing premature labor in the case of a patient who. in a former gestation, had eclamptic attacks, but in whom at the time of the subsequent pregnancy no symptoms of toxemia were present, was an important one. The speaker had completed the period of gestation in a number of cases of this sort, and believed such action entirely justifiable, although it can not be denied that a woman might go through a number of pregnancies normally before the occurrence of a second series of eclamptic seizures.

Dr. LONGYEAR—Would you advise the induction of premature labor under these circumstances if there are no symptoms whatever of renal insufficiency?

President ROSS—Yes. (The President then reported a case in which he had practiced it.)

Dr. RUFUS B. HALL of Cincinnati, looked upon such a doctrine as extremely dangerous and strongly opposed it. Simply because a woman at some previous time had had eclampsia was not sufficient reason for terminating gestation prematurely when no symptoms of toxemia were present.

Dr. POTTER, in closing the discussion, said the occurrence of albuminuria was a danger signal, but that decrease in the daily amount of urea excreted by a pregnant woman was still more valuable as a diagnostic sign. The violent production of premature labor was never justifiable. If eclamptic attacks occurred some time previous to labor the physician might take time in emptying the uterus, but in the intrapartum variety, the cervix should be carefully dilated by means of a steel dilator and the hand, and, if necessary, forceps applied and the fetus delivered. He had accomplished this within three hours when the cervix was rigid, without lacerating the tissues, and had saved the life of both mother and child.

Dr. H. W. LONGYEAR of detroit, read a paper on

PUERPERAL DIPHTHERIA,

the object of which was to bring before the profession the fact that the Klebs-Loeffler bacillus is a potent factor in the etiology of puerperal infection, six cases being reported in proof of the position of the writer. The diphtheritic character of each case was determined not only by clinical evidence, but by bacteriologic examination made by the bacteriologist of the Detroit Board of Health. Five of the cases recovered and one died, the one death being the only case in which antidiphtheritic serum was not used.

The writer recommends bacteriologic examination in all cases of puerperal infection, condemns curetting in all cases where a membranous exudate is present, and recommends the use of antidiphtheritic serum, the intra-uterine application of a strong solution of iodin and carbolic acid at the beginning of treatment, drainage of the uterus by a tube, intra-uterine irrigation with antiseptic solutions, bi-hourly vaginal injections of hydrogen peroxid, and the usual supportive treatment with quinin and whisky. In mixed cases of Klebs-Loeffler bacillus and streptococcus, he would first use the antidiphtheritic serum, and then in twenty-four to forty-eight hours, begin the use of the antistreptococcic serum. He believes that the true character of this form of infection has not been heretofore recognized, but that it will be found to be more or less prevalent in all localities in which diphtheria exists if sufficiently critical examinations are made. The physician and midwife are warned to use especial care in such localities, as the postpartum parturient canal furnishes the most favorable soil for the growth of the Klebs-Loeffler bacillus.

Dr. JOHN M. DUFF of Pittsburg, followed with a paper on

THE SOURCE OF PUERPERAL SEPSIS.

The source of puerperal sepsis he said was given by the authorities as contagion from a woman similarly affected, from suppurating or decaying tissues, from putrefying substances within or without the body, and from zymotic diseases, especially erysipelas and diphtheria.

The exact source in any given case was not always easy to determine. In a large proportion of cases, however, a careful inquiry would be rewarded with the revelation of a source. When found it generally proved to be one which could have been avoided.

Aseptic midwifery had done much to prevent puerperal sepsis, and consequently to lower the rate of mortality following childbirth. He had heard and read remarks by members of the profession in sentiment expressing the opinion that the accoucheur who was so unfortunate as to have a case of puerperal sepsis occur in his obstetric work was guilty of malpractice. Such expressions he thought were extravagant and were not warranted by our present knowledge and experience. Sepsis does occur sometimes despite the best efforts of the practitioner to prevent it. While he believes puerperal sepsis can not always be prevented, he does believe that with ideal surroundings, with a careful and skilful physician, supplemented by an educated and conscientious nurse, the number of cases could be reduced to a minimum. His observations teach him that while on the one hand there was no attempt at aseptic or antiseptic precautions, there was frequently too much reliance placed upon antiseptics. For instance, a well known member of the profession had said in his hearing a short time since that he felt perfectly safe in going to attend a case of labor after waiting upon a case of erysipelas or diphtheria, if he washed his hands well in a strong bichlorid solution. Dr. Duff thinks his patients will be safer if he went to them under such circumstances with fear and trembling, which would cause him to perform further ablutions if possible.

Without discussing at length the different known sources of infection or defining the varieties of sepsis, the author reported fifty cases of puerperal sepsis that had come under his observation.

These two papers were then discussed together.

Dr. A. GOLDSPOHN of Chicago, said such papers as the one presented by Dr. Duff were calculated to do a great deal of good. The old idea was still prevalent that puerperal fever was something specific. This was a mistake. It was an infection, just the same as a phlegmon or other inflammation which occurs in any other part of the body. The cause of it was thoroughly settled, viz., septic germs. Men who had labored exhaustively in Europe on this subject had come to the conclusion that the most dangerous germ of the disease was the streptococcus, which was present in about 4 per cent. of the cases.

Dr. LEWIS S. MCMURTRY of Louisville, said physicians were apt to think that because puerperal sepsis was discussed a number of times and so much had been written about it, that professional sentiment was crystallized and that it was a work of supererogation to agitate the subject, but if we would look around us in our respective localities we would find that the number of deaths from puerperal sepsis is very large. He sometimes thought that we do not realize at the present time, in large cities and in country districts, how great the mortality is from this altogether preventable disease, and until the mortality is reduced very materially the subject should be discussed repeatedly and published to the profession, showing the responsibility and duty that rest upon practitioners.

Dr. CHARLES G. CUMSTON of Boston, spoke of the principal cause of puerperal sepsis from a pathologic standpoint. In 1893 he conducted a series of experiments with reference to the bacterium coli. Among the specimens and autopsies that he performed in view of ascertaining the virulence of this organism he had five cases of puerperal septicemia, in all of which the uterus was carefully examined. The folds of the membrane lining the uterine cavity contained the bacterium coli, as was subsequently proven by cultures. Two of the uteri were removed by the vaginal route, and on the other three patients he performed autopsies. He could not give the clinical history of the cases, but only the anatomic and bacteriologic findings. A second cause of puerperal septicemia, and a very potent one, was the gonococcus, in that it prepares the way for pus producing organisms to enter the uterine cavity and thus set up infection.

Dr. JAMES F. BALDWIN of Columbus, Ohio, stated that in three cases of so-called puerperal fever that had come under his observation the infection was found to be due to appendicitis, and he supposes it was attributable to the bacillus coli communis. Two of the cases were operated on and recovered. The third case was operated on by another surgeon and died.

Dr. WM. WARREN POTTER of Buffalo, drew attention to the point that in discussions on certain papers presented to societies, and even in magazine articles, there was a disposition to drop from the literature of the subject the term puerperal fever. There were some old fashioned things that the profession need to cling to because they were good, but puerperal fever was no longer recognized as a distinct entity. The term was misleading in itself, because it leads to an erroneous pathology and an equally erroneous treatment.

Dr. ADAM H. WRIGHT of Toronto, said that in the majority of cases of puerperal sepsis the poison comes from without and the condition can be avoided. It is a preventable disease.

Dr. EDWIN WALKER of Evansville, Ind., said that it was a much more rational thing to dry out the genital tract than to wash it out. He would admit that even if the genital tract was dried out we could not get rid of all the germs, but we could deprive them of their nourishment. If we use a douche of clean water we furnish the germs a pabulum for their nour ishment. In puerperal sepsis he would advise wiping out the genital tract rather than douching it.

President Ross said he had seen a large number of cases of puerperal sepsis in consultation, owing to the fact that the patients had either pus tubes, pelvic abscess, or some such condition present, although he did not do an obstetric practice. He gives the causes of puerperal sepsis as follows: 1. Gonorrhea. 2. Retained placenta or membranes. 3. Dirty hands and instruments. 4. Lacerations of the cervix and perineum, improperly repaired or protected. 5. Intra-abdominal disease or tumors.

Dr. Albert Vander Veer of Albany, said he was quite sure that he reiterated the experience of other abdominal surgeons when he said that it was sad to witness the amount of ignorance that existed in regard to careful aseptic obstetric work. If we are to use serum therapy, it is very essential to make a differential diagnosis, as was touched upon by Dr. Longyear, and the speaker fancied that the future history of this work would be in the direction of the serum of streptococci. The cases must be seen as early as possible.

Dr. Albert Goldspohn of Chicago, said the gonococcus was not the exciting, but merely the predisposing cause of puerperal sepsis. There was no case of puerperal sepsis on record in which the gonococcus alone was the cause of the trouble. Other pus microbes were present in this condition, and the infection was a mixed one.

First Day—Afternoon Session.

Dr. Adam H. Wright of Toronto read a paper on

TOXEMIA OF PREGNANCY,

in which he said that the chief symptoms of this condition were salivation; disorders of digestion, with sometimes a peculiar taste, and constipation; general malaise; anemia; nervous disturbances or headache; disorders of vision; irritability; deficient excretion of urine or some of its constituents, and albuminuria. To speak briefly, he thought any sign of the slightest departure from ordinary health during pregnancy should make us suspect the advent of general toxemia, and should receive careful investigation and thorough treatment. If, for instance, there be general malaise, with slight headache, but no albumin in the urine, let us not be deceived, since albuminuria was only one of the symptoms of systemic poisoning, and sometimes the last to appear. Its absence proved absolutely nothing.

Coming to the treatment, reference was made to milk diet for toxemia or albuminuria of pregnancy. He believes that a purely milk diet is good for young babes and calves, but he does not think that it is suitable for adult human beings. Yeo, in his admirable book on "Food in Health and Disease," shows clearly that milk is not a suitable food for healthy adults because it contains an excess of albuminates and fats, and that it should be mixed with other foods, especially the carbohydrates. If it be conceded that milk alone is not the best food for healthy adults, it is difficult to conceive how it can be the most suitable in any case of disease.

In connection with his results in the Burnside Hospital, in nine years they have had sixty-five cases of toxemia with albuminuria with two deaths, both from eclampsia. One of these two patients came into the hospital in a dying condition with eclampsia, having received no previous treatment. In the sixty-five cases mentioned there were many cases where the albuminuria and other symptoms were only slight.

In conclusion, the author enumerated the main points in his treatment as follows: 1, a carefully selected mixed diet with plenty of water, plain and mineral, lemonade without sugar, etc.; 2, rest, good hygienic surroundings and proper clothing; 3, the regular and persistent use of purgatives for weeks or months, with a preference for epsom salts; 4, a warm daily bath; 5, the induction of abortion or premature labor in rare cases.

THE TREATMENT OF PUERPERAL ENDOMETRITIS BY THE CAROSSA METHOD.

By Edward J. Ill, M.D., Newark, N. J.

There appeared a pamphlet early in the winter of 1896 by K. Carossa, describing a method which consists simply in the use of alcohol as an irrigating material, supplemented by gauze packing of the uterus in such a way that the alcohol finds its way into the most distant recesses of the uterus. A catheter is introduced into the uterus and this organ filled with absorbent gauze in a lightly, but thorough fashion. At the external end of this catheter a funnel is attached through which a 20 to 25 volume per cent. of alcohol solution is poured so as to flow into the gauze with which the uterus is filled. The quantity to be used is from 30 to 50 c.c. every hour, day and night. In three to six days the gauze is removed.

The originator of this method presents some fantastic theory of the evaporation of alcohol which the author of the paper can not agree with, and to which Dr. Carossa attributes his results. Dr. Ill has used the above method, slightly modified, with good results and recommends it for further trial, especially so on account of its great simplicity.

Dr. Rufus B. Hall of Cincinnati, discussed some of the

SEQUELÆ FOLLOWING SUPRAVAGINAL HYSTERECTOMY.

He said he thought the profession had been too hasty in approving the present methods. They had taken the stand that there was nothing more to be desired; the operation was complete. While the Doctor had no new method to offer, he hoped the discussion of his paper would suggest something to improve the technique of the present methods.

He referred to objections to the extraperitoneal method, and then spoke more in detail of total extirpation. He was one of the first to advocate and make this operation, and he had attained excellent results with it. However, it did not meet his ideas of a perfect operation. The final results were good, but there was a primary difficulty that was disagreeable. Suppuration necessarily took place about the ligatures on the sixth or seventh day, causing a slight rise in temperature. To overcome the suppuration, he used specially prepared catgut for the ligatures below the peritoneum. He found the catgut unreliable on account of the danger from hemorrhage through slipping of the knots, and so abandoned its use.

After seeing Dr. Kelly of Baltimore, in 1895, make the supravaginal operation with his modifications in the technique of the Baer method, Dr. Hall adopted that method. He operated according to it forty-six times, but was not pleased with his results. Eleven of the cases had post-operative sequelæ, due to the buried ligatures. All the patients made good primary recoveries, only one showing any signs of trouble earlier than the seventh week. This one had a discharge of pus from the vagina at the end of the fourth week. The discharge disappeared to return again at intervals of a few days to four or five weeks, and only ceased when the ligatures were removed. The other cases had similar histories except that they did not have any trouble until from four to eleven months after the operation. Within a few days after the ligatures were removed, the patients were well and have remained so, except two. These two, one sixteen and the other eighteen months since the operation, are still having trouble as the ligatures have not all come away. The Doctor said he knew the material was not at fault or there would have been trouble immediately following the operation. Besides, the same material was used in other operations and no trouble resulted. He said he believed a large percentage of the patients so operated on would certainly have this trouble. The general surgeons are abandoning the use of silk, silkworm gut and silver wire in Bassini's operation for this very reason, and he felt it only logical for the gynecologist to expect to have to do the same. He urged the other gynecologists to tell their results with this method and compare notes.

The Doctor closed his paper by saying that in spite of the fault he had to find with total extirpation, he preferred it to supravaginal hysterectomy as practiced by Baer and modified by others. He felt more certain of his final results with the former method.

Dr. George M. Hughes of Philadelphia read a paper on

THE SEQUELÆ OF DEAD LIGATURES AND SUTURES.

While assisting Dr. Joseph Price in his abdominal work the essayist had recently been greatly interested in a number of cases in which he reopened the abdomen for the freeing of adhesions and the removal of dead ligatures and sutures. Sutures and ligatures should be of that material which is easiest sterilized and which combines great strength in a small bulk. It was always preferable to use a material capable of being rendered aseptic by heat or boiling. If this could be done, we could at all times have the means at hand to render our ligatures perfectly sterile. For this purpose he finds that for pedicle ligatures and for bowel work the twisted Chinese silk is the best, of finest quality and sufficiently small to secure safe tying; for closure of the abdominal incision silkworm gut and the through and through method. What becomes of the ligatures? If small and sterile, they become encapsulated and rapidly absorbed. If plaited ligatures and large hawsers are used, whether infected or not, they are never absorbed, but their presence as foreign bodies give a train of symptoms unbearable in their distress and constant in their duration. The same conditions are found about the pedicles, only here we have the adhesions of omentum, large and small bowel and bladder to both the pedicles. To obviate post-operative sequelæ we should select that method of applying ligatures which gives safety with the least quantity of material. For pedicles the simple figure of-eight tie is the best, in that it gives a firm, small, strong tie and one not liable to slip. The pedicle is then cut cone-shape. The pedicle must be made as small as possible; large pedicles are prone to behave badly, and to this is due the post-operative adhesions of omentum, bowel or bladder. To illustrate his remarks the essayist selected and reported five instructive cases.

(*To be continued.*)

SELECTIONS.

The "Plaque-System" of Filtration of Water Supplies.—Engineer Fischer of the public works department of the city of Worms, Germany, has invented a filtration method that is claimed to have decided advantages over the ordinary sand or gravel beds. The basis of the new system is found in the fact that clean, sharp sand when mixed in due proportion with finely pulverized glass, which may be derived from the waste of a high temperature, may be hardened in any desired form. The inventor in this case hit upon the plan of molding this porous cement into hollow plates or "plaques" about forty inches square and eight inches thick, that is, with walls three inches in thickness and about two inches of hollow space at the center of the plaque. The system is sometimes spoken of as the "plaque system of filtration." In constructing the filtering plant, these plates are set upright in groups or batteries of any number, according to the desired size and capacity of the establishment, and are ranged along the lower portion of one or more tanks of hydraulic masonry, where they can be covered to a depth of three or four feet with the water to be filtered. The water is then forced by its own pressure through the porous walls of the plates into the interior hollow space, where it trickles down and is drawn off through pipes laid at the bottom of the tank, to the reservoir which receives the filtered water. These discharge pipes are rigged with cocks so that each plate and group of plates may be isolated for cleaning or other purposes while the adjacent batteries are in operation. The water, in passing through the three-inch walls of vitrified sand, is filtered as perfectly as by traversing three feet of loose sand or gravel in the ordinary sand filtering process. The plates being set upright and close to each other increase from eight- to ten-fold the filtering surface that may be condensed within any given superficial area, thus securing an important economy of space between frost-proof constructions, and where, as is often the case, land is costly and difficult to obtain. According to an official report by M. Janssen of the University of Brussels, who made an exhaustive study of the whole subject at Worms, that city began in 1889 the filtration of Rhine water for general purposes by the ordinary sand filtering process similar to that then used at Berlin. With a filtering surface of 1,300 square meters (approximately 13,000 square feet), 3,000 cubic meters (792,510 gallons) of water were filtered in twenty-four hours. This supply proved insufficient for the city, and it became necessary to construct an addition to the filtering plant, the cost of which, on the sand filter plan, was estimated at $30,000. It was then that the Fischer system was given a practical trial. Instead of occupying new land and building additional constructions, one of the ten vaults containing the sand filters already in use was isolated, cleaned out and the space filled with a battery of five hundred plates of the Fischer pattern. The whole cost of the change thus made was about $9,600, and the new filters, occupying one-ninth as much space as the sand filters, doubled the filtering capacity of the entire installation. In other works, five hundred Fischer plates costing, set up and ready for operation, $9,600, and occupying only 130 square meters of space, filtered as much water as the sand filters which occupy 1,170 square meters of space and cost $30,000. To substitute the Fischer plates for sand throughout the entire establishment would be to increase the filtering surface from 1,300 to 10,000 square meters (approximately from 13,000 to 100,000 square feet) and multiply by ten the daily filtering capacity of the plant. From a long series of analyses and careful observations by the sanitary authorities at Worms, it appears that the efficiency of the two systems of filtering, which are there worked side by side, are practically identical, so far as regards their effect on the chemic purity of the water, but the percentage of bacteria left by the Fischer process is somewhat greater than is left by the sand filter when clean and in good working condition. This, however, is not considered a defect of practical importance. The water delivered by the new filter at Worms, as well as at the other places where they are in daily use, is certified by high and impartial authority to be thoroughly purified and fitted for drinking, as well as for culinary and manufacturing purposes. In addition to the city of Worms, the following towns have adopted this system: Kiel, Landberg (near Berlin), Madgeburg, Frankenhausen and Winterthur, and it is thought possible that certain of our inland cities, like Cincinnati, Louisville and Cairo, may find in the experience of the above towns an aid to the solution of the problem of the safe utilization of their near-by river supply.—*Consular Reports.*

Lord Lister on Physiologic Research.—Lord Lister has made an important and interesting address on the subject of modern pathologic research at the opening of the Belfast Physiological and Pathological Laboratories, an extract from which as published in the *British Medical Journal* is given below:

"There are people who entertain exaggerated views," he says in effect, "regarding the work that is accomplished at such laboratories. There are people who do not object to eating a mutton-chop, people who do not even object to shooting a pheasant with the considerable chance that it may be only wounded and may have to die after lingering in pain, unable to obtain its proper nutriment, and yet who consider it something monstrous to introduce under the skin of a guinea pig a little inoculation of some microbe to ascertain its action. Those seem to me to be most inconsistent views. With regard to all matters in which we are concerned in this world, everything depends on the motive. A murderer may cut a man's throat to kill him; any one of you medical students may have to cut a man's throat to save his life. The father who chastises his son for the sake of the good of his morals is a most humane man; a father who should beat his son for the mere sake of inflicting pain upon him would be an inhuman monster. And so it is with the necessary experiments upon lower animals. If they were made, as some people seem to assume, for the mere sport of the thing, they would be indeed to be deprecated and decried; but if they are made with the wholly noble object of not only increasing human knowledge, but also diminishing human suffering, then I hold that such investigations are deserving of all praise. Those little know who lightly speak on these matters how much self-denial is required in the prosecution of such researches when they are conducted, as indeed they always are, so far as I am aware, with the object of establishing new truth. The exercise of a little charity might lead those who speak of us as inhuman to reflect that possibly we may be as humane as themselves.

"The profession to which I have the great honor to belong is, I firmly believe, on the average, the most humane of all professions. The medical student may be sometimes a rough diamond; but when he comes to have personal charge of patients, and to have the life and health of a fellow creature depending on his individual care, he becomes a changed man, and from that day forth his life becomes a constant exercise of beneficence. With that beneficence there is associated benevolence; and in that practical way our profession becomes the most benevolent of all. If our detractors knew this, common sense would enable them to see that our profession would not be unanimously in favor of these researches if they were the iniquitous things which they are sometimes represented to be.

"I have been interested in the following account of a part of Pasteur's work on rabies: It had been established that the introduction of a portion of the brain of a mad dog under the skin of a healthy animal was liable to cause rabies, and Pasteur had reason to believe that it was principally in the nervous centers that the poison accumulated. He felt a very strong desire to introduce some of the poison into the brain of an animal; but he was a peculiarly humane man. He never could shoot an animal for sport. He was more humane than the great majority of human beings, and for a long time he could not bring himself to make the experiment of trephining an animal's skull and introducing some of the [illegible] of rabies into the brain. He [illegible] sirous [illegible] establish the patholo[illegible] he s[illegible] one occasion, when he was absent from home, one of his assistants did the experiment, and when Pasteur came back he told him that he had done so. 'Oh!' said Pasteur, 'the poor creature! His brain has been touched. I am afraid he will be affected with paralysis.' The assistant went into a neighboring room and brought in the animal, which was a dog. It came in frisking about and investigating everything in a perfectly natural manner, and Pasteur was exceedingly pleased, and although he did not like dogs, yet he lavished his affection upon that particular animal and petted it; and from that time forth he felt his scruples need no longer exist. So soon as our poor selves are directly concerned our objections vanish into thin air; a tiger threatens to invade our camp; who would care much about what kind of trap was set for it, or what suffering the trap caused the animal, so long as it was caught? When the matter affects only the welfare of others, including that of generations yet unborn, the good done does not appeal to the individual and the objector sees only the alleged horrors of modern scientific investigation; of which horrors, however, he quickly loses the sense as soon as he becomes personally concerned."

PRACTICAL NOTES.

Sub-diaphragmatic Abscesses are usually fatal if left to themselves, but the symptoms are so contradictory that they are rarely diagnosed during life. The experience of H. Graves has been therefore exceptional, as he reports six cases in his practice in Sweden, diagnosed and operated in time to save all but one.—*Hygeia*, 1.

Belladonna for Tuberculous Abscesses.—Hamant recommends the use of a belladonna salve (extract bellad. 3 to 30 grams vaselin), for the abscesses caused by the external eruption of an underlying tuberculous focus, as he has found it possessed a favorable, even perhaps a specific effect in such cases, the more remarkable as it has no effect on non-tuberculous ulcerations.—*Therap. Woch.*, July 25.

Some Points in Scarlet Fever Cases.—Dr. Joseph W. Hickler of Orange, N. J. (New York Academy of Medicine meeting, June 3), in his experiments for an immunizing serum, discovered that the mucus of the throat and mouth contained the contagium of scarlet fever, and that the early eruptive stage was very infective because of the discharges from the mouth and throat. He found the average period of incubation to be thirty-two hours; time before vomiting, twelve hours; shortest time for desquamation, three days; and the longest, nine days.

Decalcification of the Arteries; Rumpf's Treatment of Angina Pectoris.—Professor Rumpf of Hamburg ascribes the etiology of certain affections, notably angina pectoris, to accumulations of lime in the arteries, and has secured remarkably favorable results in twelve cases in which he has produced increased elimination of lime through the urine and feces, while reducing to the minimum the amount of lime ingested. He denounces the use of milk in cardiac affections, as it is rich in calcareous salts, and restricts his patients to the following diet per day: Meat, 250 grams; bread, fish, potatoes and apples, each 100 grams. This menu contains 93 grams of albumin, 14 of fat, 93 of carbohydrates, and furnishes 892 calories. Adding 100 grams of butter, 100 of cream and 50 of sugar, the number of calories is 2000. It contains ten times less lime than a strictly milk diet and three to four times less than the Hoffmann substitute diet. The potatoes can be replaced by an equal quantity of green peas, beans or cucumbers, but he forbids any milk, eggs, cheese, beets, spinach, rice, or any food rich in lime. For a drink he orders distilled water, or at least water boiled and cooled. His medication is limited to the following, to be taken during the day: Sodium carbonate, 10 grams; lactic acid, q. s. to saturate. Add lactic acid, 10 grams; simple syrup, 10 grams, and 200 grams aq. dest. This medication can be employed for a long while without inconvenience. The amount of lime eliminated with this treatment increased 50 to 52 per cent. Rumpf does not hope to cure, but merely to arrest the development of the affection, and his truly remarkable success in relieving severe cases of angina pectoris should encourage others to persevere in this line.—*Presse Méd.*, July 17.

Importance of the Motor Functions of the Stomach.—According to J. Boas of Berlin, we have been inclined to ascribe altogether too much importance to the chemic action of the stomach as the chief factor in normal digestion, when in fact its motor capacity is the most important. He asserts that the hydrochloric acid of the stomach is not a secretion necessary to the integrity of the organism nor of the stomach, also that even with copious secretion of hydrochloric acid, fementation occurs as soon as any serious mechanical obstruction intervenes, but adds that ulcerations of the gastric mucosa may produce limited fermentation even without mechanical obstruction to the outflow. It is therefore the main task of gastric therapeutics to cure disturbances in the motor functions of the stomach. In determining insufficiency, inflation and illumination are less reliable than the Leube or Boas test supper. (The latter consists of a cup of tea, two wheat rolls with butter and cold meat.) If food is found in the stomach in the morning following this meal, there must be great mechanical disturbance of the process of digestion; much gastric juice with it signifies hypersecretion; mucus, gastritis; bile, some obstruction in the duodenum or upper jejunum; stearic acid, fermentation of fats; alcohol, lactic acid, carbonic acid, marsh and hydrogen gas indicate fermentation of carbohydrates; sulphuretted hydrogen, etc., fermentation of albumin. Of the micro organisms, the sarcinæ thrive best on hydrochloric media; the bacilli on lactic acid fermentation; scantily in benign ectasia with hydrochloric acid. Saccharomyces are found in every case. Removing the cause is the first indication; extirpating cancer of the pylorus, stretching the contracted pylorus (Oreta), pyloroplastics (Heineke-Mikulicz), separation of adhesions. Gastro enterostomy may cure in benign cases, even without removing the cause. Surprising success is sometimes attained by palliative measures. He classifies the indications for the diet as follows: 1, "insufficiency with permeable pylorus and retained (increased) secretion of gastric juice, require restriction of the fluids allowed; 2, pylorus contracted, normal (increased) secretion of gastric juice, indicates that fluid and soft food will be better digested, especially milk in small amounts; 3 and 4, suppression of the secretion of the gastric juice, carcinoma with stagnation and severe gastritis. Fluid food is best adapted to all these cases, taken in small, frequent meals. In benign stenosis with abundant secretion of gastric juice, the best diet is animal albumin with restricted non-nitrogenous food; in stenosis of the pylorus with lack of gastric juice, carbohydrates and fats are preferable, with easily assimilated vegetable albumin. In every case milk must be tried. If it is impossible to maintain the nitrogenous equilibrium of the organism by the food taken into the stomach, which shows imperfect diuresis, it must be supplemented per rectum. As the tissues dry out rapidly in such cases, the introduction of salt solution is valuable; also of alimentary fluids, such as milk with eggs, red wine, starch and salt. Irrigation of the stomach is only required in severe stagnation, but can be employed occasionally, if care is afterward taken to entirely remove all the water. It should be made late at night or early in the morning, with salicylic acid added, 3 to 1,000. The effect of massage and electricity is not yet sufficiently determined. There is no medicine for motor insufficiency, although strychnin, orexin, cetrarin and columbin have been recommended. To curb fermentation, salicylic acid (0.3 to 0.5 gram), or salicylate of soda (1 to 2 grams) are best, administered in the evening. Sodium bicarbonate, magnesia and Carlsbad salts expel the gases. Hydrochloric acid can be administered when it is absent, and opiates and laxatives are demanded in certain cases.—*Memorabilien*, July.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 28, 1897.

KLONDIKE NOSOLOGY.

Since the appearance of "Medical and Anthropological Notes on Alaska," by Dr. IRVING C. ROSSE of Washington,[1] who went on Arctic voyages in search of the exploring yacht *Jeannette* and the missing whalers, nothing of importance has been contributed to our medical or anthropologic knowledge of the glacial zone. In addition to writing the "Cruise of the *Corwin*" the Doctor, being a Fellow of the Royal Geographical Society, wrote an account of "The First Landing on Wrangel Island with some Remarks on the Northern Inhabitants," besides contributing to WOOD'S "Reference Hand Book of the Medical Sciences," the articles on "Scurvy" and on "Cold," which embody much of the information and experience gained on the fore-mentioned voyages.

Now that the wild and thoughtless rush to the Alaskan gold fields is uppermost in the public mind, everything relating to our far-away hyperborean possession calls forth an intensity of interest that makes all Alaskan matters pertinent and brings them to the front once more.

Of the many facts of scientific interest observed and recorded, those of a medical and anthropologic nature remarked by Dr. ROSSE may be classified according as they concern the effects produced upon the visitors by the peculiar conditions under which they found themselves, and those phenomena observed among the aboriginal inhabitants, owing in part to those same conditions, become permanent, and in part of course to race idiosyncracies.

Under the former heading we notice that a discrepancy was often observed between the record of the thermometer and the feeling of the observer, or, as the writer expresses it, between physical and physiologic cold. With the thermometer at 45 degrees F., the temperature was described as uncomfortably warm, and again at 60 degrees F., the direct sun heat was *once almost overpowering.* Whereas the experience of travelers in other latitudes, as for example in the Peruvian Andes, is cited as showing a keen and penetrating cold at the same temperature, 60 degrees F. As Dr. HAYES went swimming in a pool of water on the top of an iceberg in Greenland, and as other northern travelers have bathed in Siberian waters, so one writer took his plunge into the icy Arctic Sea on one of the physiologically warm days, and enjoyed it. The whole subject of heat production and temperature equilibrium among northern peoples as well as in the marine mammals is one of exceeding interest, and the reported facts of a physiologic rise of temperature after exposure to cold water or air in temperate climes may possibly indicate some special adaptation of thermic functions in these hyperboreans. At all events it is much to be regretted that want of instrumental facilities prevented any observations being made on the temperatures of the human subject under varying conditions; especially unfortunate is it in view of the suggestions as to the value of alcoholic beverages in cold climates. Contrary to the teaching of physiology regarding the vasomotor effects of alcohol, and contrary also to what has been often claimed, as in a recent paper by Dr. LEFFMANN before the Philadelphia County Medical Society, to be the experience of Arctic explorers of the deleterious effects of alcohol among northern voyagers, we find that Dr. ROSSE cites numerous Arctic travelers, and coincides with their testimony, to the effect that the moderate use of alcoholic beverages is found to be advantageous in the severe weather of the high latitudes. But it is possible that the discrepancy is more apparent than real, for we have no thermometric records on the spot to offset the physiologic evidence, while alcohol seems to be one of the best antiscorbutics, and we know scurvy to be one of the great banes of northern voyagers. The "heavy-headed revel which HAMLET confessed his countrymen to be addicted to, and to which travelers in general have observed a tendency in northern peoples, may be, as one author rather intimates, but nature's call for a protective against the inclement conditions of life; but if so, nature seems in some danger of overdoing the matter, for we read of the rapid depopulation of St. Lawrence Island, where one thousand of the inhabitants have perished in three years, and many villages are already quite extinct, a result ascribed to too much of the "bay rum," "Florida water," and other euphonious brands of poor alcohol which struggle past the revenue officers, and for which the Eskimos exchange their furs with great eagerness. Much of the responsibility for this physical deterioration ascribed to intemperance properly belongs to the vile liquors used, and again to starvation. But certainly more exact observations as to the effects of alcohol in the human economy in cold climates are much to be desired.

---

[1] Government Printing Office: 1883.

The northern voyager seems to be, as a rule, tolerably free from acute bronchitis or pulmonary disorders while exposed to severe cold, but there is a marked tendency to the development of such affections after his return to a temperate climate. This was observed in the crew of the *Corwin*, as it has been in other individuals. On the other hand the natives seemed constantly suffering from colds and coughs, a fact which appears to show a greater cold-resisting power in the white race.

Some curious auditory and optic phenomena are recorded. The irregular refraction of the atmosphere at some points, taken in connection with the wonderful clearness in others, gives rise to remarkable deceptions of the vision. The distinctness with which small stones and other objects on a mountain side can be seen at times bewilders the vision, while the vagaries of the mirage and the blending of the real with with the unreal leaves one in doubt as to what he actually sees. The sound of a boatswain's orders, and of laughter and conversation at a distance of two miles, the noise of one's own beating arteries on a still day, and the repetition of echoes, in one case to nearly a hundred times after a pistol shot, are some of the freaks of acoustics.

The diseases to which the Innuit population are specially subject are scurvy, syphilis, and an epidemic which seems to have been of the nature of grippe or a species of pneumonia of an extremely asthenic type. No postmortem evidence was at hand to show whether the pathologic condition corresponded with that of the type of the disease common with us. Lung troubles in general are seen to follow a mild winter. Intermittent fever at Cook's Inlet, apparently originating on a bluff several hundred feet high, in houses exposed to a breeze direct from the inlet, is a fact more interesting than explicable. Rheumatism and gastric derangement, the latter often from overeating, are not rare.

Alaska is a favorite place for surgical operations, wounds healing with great rapidity. The presence of ozone and the absence of germs are believed to be the cause of this. Hysteria is a luxury which the female Eskimo is by no means willing to relinquish entirely to her white sister, and nervous diseases we find to be quite frequent. Our author, with much less levity for the narcotic weed than for alcohol, ascribes neurotic diseases to the senseless and filthy habit of using tobacco. Certainly they can not be considered as the sequelæ of civilization.

We may merely mention that the popular notion of the typical Eskimo cranium is said by Dr. ROSSE to be incorrect. Instead of the pyramidal skull, with prominent superciliary ridges, occipital protuberance, and zygomatic arches, and with small brain capacity, one finds the type to have a large facial angle (eighty degrees), and a brain capacity equal to the average Frenchman or German. The squamoparietal suture has not the convexity noticed in the chimpanzee and the mound-builder, and the index of the foramen magnum is about the same as in European crania. According to Dr. ROSSE, the facts regarding the natural intelligence of the Eskimo correspond with these cranial appearances, and the northern people have by no means the dulness and slowness of understanding which some have ascribed to them. Neither have they any coldness of the passions corresponding to the thermometric range of their climate. Unchastity is as common among them as among the hottest savage that swelters under the tropic sun, and it is evident that something more than external ice and snow are necessary to cool the desires of the human animal.

Much more of interest and novelty is told of the social, ethnic and other peculiarities of the Eskimo, of which space forbids further notice.

The instructive and practical value of the forementioned views of Alaska may be of great service to those seeking medical information concerning a part of the country almost unknown. Doubtless many lives will be lost and much suffering ensue from neglect of the proper precautions of a simple nature by the unprepared who, seized with the thirst for gold, brave the dangers beyond the north winds in a region best described as the "abomination of desolation." However, with the continued supply of the precious metal such a state of affairs can not long exist, for in a short time the all-powerful combination of gold and Anglo-Saxon energy will bring with it the iron horse and the electric installation, which will change present Klondike rigors into those of comfort and even luxury.

THE GERM OF YELLOW FEVER.

We have been much interested in the account given by SANARELLI of his bacillus icteroides, the recently announced *vera causa* of yellow fever. We have had so many announcements during the past twenty years of the discovery of this germ that we may be excused for hesitating to accept the cry, "Eureka!" Nevertheless SANARELLI's claim to the identification of the bacillus appears to have been based on satisfactory experimentation and to have met with official acknowledgment in South America, if we may credit newspaper accounts of a $10,000 premium awarded him for his discovery.

He found his bacillus mixed with the coli bacillus, staphylococci or streptococci, or he was unable to find it owing to the cadavers being invaded by other microbes which caused the total disappearance of the specific bacillus. He found it in the circulating blood and in the interior of the tissues, but never in the gastro-intestinal contents, hence he holds that the virus of yellow fever does not reside in the digestive tube but is manufactured in the organs or in the blood itself.

In plate culture in ordinary gelatin the bacillus icteroides forms roundish colonies, transparent and granular, which during the first three or four days present the appearance of leucocytes. The granulation of the colony becomes continuously more marked, and usually a central or peripheric nucleus, completely opaque, is delineated. With time the entire colony becomes opaque, but does not liquefy gelatin. Streak cultures on gelatin solidify obliquely, forming brilliant opaque little drops similar to drops of milk.

The culture on agar-agar presents, according to Sanarelli, a diagnostic means of the first importance. When the colonies are developed in the incubator they are roundish, gray, a little iridescent, transparent, with a smooth surface and regular margins; but if instead of making them grow at a temperature of 37 degrees C. they are left to grow at a temperature of 20 to 30 degrees C., the colonies are like drops of milk, opaque, prominent, and with pearly reflections, different from those developed in the incubator. This difference can be utilized by exposing the cultures for the first twelve to sixteen hours to the temperature of the incubator, and then keeping them for twelve to sixteen hours more in that of the room. The colonies then show a flat central nucleus, transparent and bluish, surrounded by a prominent and opaque zone, the whole resembling a drop of sealing-wax. This character, which can be obtained even in twenty-four hours, serves to establish in the most rapid and certain manner the bacteriologic diagnosis of the bacillus icteroides. It is a facultative anaerobe, does not resist Gram's stain, slowly ferments lactose, more actively glucose and saccharose, but is not capable of coagulating milk. It strongly resists drying, dies in water at 60 degrees, and is killed in seven hours by the solar rays, but lives for a long time in sea water.

Eighteen years ago Dr. Sternberg commenced his bacteriologic investigations into the etiology of yellow fever. They were made in Havana in 1879, 1888 and 1889; in Rio de Janeiro in 1887; in Vera Cruz in the same year and in Decatur, Alabama, in 1888. He concluded that among the micro-organisms found in yellow fever cases there was not one which by its constant presence and special pathogenic power could be shown indisputably to be the specific infectious agent. He recognized however, that there was a non-liquefying bacillus, which he called bacillus X, found generally in association with bacillus coli communis and which, as it had pathogenic properties and was not found in cadavers from other diseases, he at times felt convinced was the germ he was looking for; but scientific conservatism compelled him to withhold the announcement of a discovery in view of the fact that he had failed to find in about one half of the undoubted cases of yellow fever which he had examined; and he adds with exceeding naïveté, in his paper for the International Medical Congress at Moscow, that there have already been so many announcements of the discovery of this long sought-for microbe by Carmona, Freire, Gibier and Findlay, the fallacies of which he had demonstrated, that he was not willing to take any chances of making a similar mistake.

His bacillus as described in these early reports is a facultative anaerobe sometimes so short that it might be taken for a micrococcus. It is often united in pairs and is pleomorphous. Its growth on the surface of glycerin agar is white, cream-like in consistency and quite abundant. The superficial colonies are circular or irregular in outline with transparent margins and an opaque central portion sometimes corrugated. They are finely granular, iridescent and of a milk-white color by reflected light, but of a brownish color by transmitted light. This bacillus grows well at 20 degrees C., but more luxuriantly at 30 to 35 degrees C. It is not destroyed by exposure to a freezing mixture of ice and salt for two hours; its thermal death point is 60 to 62 degrees C. It is pathogenic for guinea pigs, still more so for rabbits.

We are aware that, in the paper prepared by Dr. Sternberg for the Twelfth International Medical Congress he affirms his belief in the identity of his bacillus X with the bacillus icteroides of Sanarelli. This bacillus he obtained from yellow fever cadavers in Havana, and concerning it he reported, in 1890: "Bacillus X, I have not obtained up to the present time in any comparative researches and consequently regard it as possibly connected with the etiology of the disease. But I have not been able to obtain any satisfactory experimental evidence upon which to base a positive claim that this is the case."

Some of the experimental evidence is opposed to the view that the bacillus is identical with Sanarelli's bacillus icteroides. Sternberg found that inoculation with the blood or the liver parenchyma of persons dead from yellow fever had no harmful effect on guinea pigs or rabbits except in occasional cases in which the bacillus of rabbit septicemia was present. He recorded a negative, however, at the end of five or six days, but Sanarelli states that his bacillus produces a cyclic febrile disease which always ends fatally in eight to twelve days. Again, the non-liquefying bacilli are not found in sufficient numbers, nor are they sufficiently constant to give support [illegible] they are the specific cause of the [illegible] berg's conclusion after many examinations of liver and blood. These bacilli when found in the tissues, were found also in the alimentary canal; but Sanarelli has not found his bacillus icteroides in the intestinal contents. Sternberg concluded that they made their way from the canal to the tissues; Sanarelli, that the poison is manufactured in the blood and in the interior of the organs.

Sternberg found his bacillus X in one-half of his cases; Sanarelli his bacillus icteroides in 58 per cent. This was the *status quo* when the latter made his convincing experiments on the dog, the monkey and on man.

Sternberg holds, and apparently with justice, that the identity of the two bacilli is obvious, claiming that unless this identity is conceded it would be difficult to admit that Sanarelli's bacillus is the germ of yellow fever, for unless it is identical with bacillus X it was not present in the yellow fever cases examined by him during his extended researches in Havana.

The fact that bacillus X is not destroyed by freezing is opposed to the view of its being the yellow fever germ; but the interesting observations of Sanarelli on the symbiosis of the bacillus icteroides with certain hypomycetous fungi appear to dispose of this difficulty and to throw light on many hitherto obscure matters relating to the etiology of the disease. Dr. Sternberg proposes at once resuming his experiments with the view of ascertaining whether his bacillus X has the pathogenic properties ascribed to bacillus icteroides by Sanarelli; and we may add that since his departure for Moscow intravenous experiments on dogs conducted under his direction in the Army Medical Museum have given characteristic results.

A CHEMIST UPON EXPERT TESTIMONY.

The address of vice-president and chairman W. P. Mason of the Chemical Section of the American Association for the Advancement of Science, at its recent Detroit meeting, dealt with a subject that has some interest to medical men, especially those who are called upon to give their opinions in courts of justice—that of expert testimony. Those of us also who make no special claims to expertness also have reason to desire, for the credit of our profession, that something should be done or said to better the status of the medical expert, and the suggestions here offered by one who is not a physician but a chemist, is an additional proof of what is not perhaps fully appreciated by us, that experts in all branches of science suffer under the same disadvantages before our tribunals. The pseudo-scientist abounds everywhere and discredits all the learned professions alike, and ignorant counsel and judges sneer at false and true experts alike. If we as physicians have suffered more in this way than specialists in other lines, it is for the reason that there are more of us, and especially because too many of our number, without necessary evil intent, permit themselves, it may be, to be led beyond the field in which they are truly experts and are not, like some others in the same position, as Professor Mason very properly says every expert witness should be, as fearless of legitimate ignorance as they ought to be fearful of illegitimate knowledge.

Assuming, however, that all experts are truthful and can clearly and tersely give an intelligent statement of their views and can aptly and clearly illustrate them, there are yet some conditions and situations in which they can be put in an entirely false position discrediting themselves, their cause and their profession, and some of these are very forcibly stated by Professor Mason in his address. In the first place, in a medical point of view, we have the ignorance and prejudice of lawyers, juries and judges. If this is felt to their disadvantage by chemists and others, it is still more appreciable by the medical expert. There is no nonsense so absurd that some educated and in some respects cultured people will not accept as scientific truth, and medicine is the one field of all others in which the credulity of the laity has run riot. This is one of the facts that we have to reckon with, and even a real expert who thoroughly knows his subject can not always relieve himself from the disadvantageous position in which it may place him "With stupidity even the gods strive in vain."

It is unfortunate that even the friendly counsel may often through their ignorance and prejudice thus embarrass the expert witness, who may often have to pray to be delivered from his friends. The hypothetic question, which has been editorially endorsed in the Journal as an ideal method of obtaining expert opinion, may be so imperfectly or clumsily made up as to be seriously embarrassing to any one who wishes to convey a correct idea of his opinion of the case. Questions may be intentionally asked requiring a categoric answer which is likely to be directly misleading, and the expert refused the privilege of making the proper and necessary explanations. The only recourse is to appeal to the court, and to claim that as the witness is on oath to tell the whole truth and nothing else, he should not be confined in his answers to statements that taken by themselves do not convey the whole truth or that may actually imply a falsehood. Professor Mason in this connection raises an interesting legal point as to what is the duty of the expert witness, should he in all cases simply answer questions or should he state facts as known to him which might convey different impressions. Lawyers seem to have rather divergent opinions as regards this question, one high legal authority maintaining that the expert is for the time the property of the side employing him and is therefore to confine his answers entirely to the questions as asked. Another admitted this to be the rule in civil cases but that the situation was different when the life or liberty of an individual was involved. Morally there would appear to be no question as to the duty of the expert, and it certainly would be advisable for the same, before going on the witness stand, to have a good understanding with the lawyer of the side employing him as to all the reservations of freedom of speech that his conscience may demand. No honest man would desire to wrong another by his sins of omission any more than he would to actually bear false witness against him, and the expert has not the advocate's plea of ignorance in his special field of knowledge.

An important practical suggestion that Professor Mason makes is that the expert should not trust implicitly the record made by court stenographers but should always seek an opportunity to examine the notes and ascertain if he is correctly reported. Court reporters are not always perfectly accurate, they sometimes leave out important statements and, at the best, they are inevitably ignorant of scientific terms and liable to misunderstand them. Hence the necessity of avoiding technicalities in the testimony as far as possible, for the sake of the reporter as well as the jury, and it is in this respect that mistakes and erroneous records are perhaps the most frequently made. If experts would always revise their recorded testimony they would escape the inconvenience they sometimes experience of being charged with statements they never made and of having such charges supported by the official record.

An expert is such only in his own particular department and should not fear to express his ignorance outside of it. It is a common practice of lawyers to attempt to draw from him opinions in regard to subjects outside his specialty and even those calling the witness may err in this way in the direct examination and be irritated if not answered to their satisfaction. It is always safest for the expert to avoid being thus misled, and while this trick is perhaps most often tried on non-medical experts, it is well for the physician also to be on his guard in this respect and not to hesitate to admit his lack of special information upon outside matters. The failure to do this has often resulted in embarrassing situations. The expert should also of course be well informed in regard to the authorities in his specialty, but should carefully avoid anything like the assumption of knowledge that is not possessed. It is much better to admit ignorance than to be caught by a lawyer's trick into admitting even the existence of pseudo-authorities, as some have done to their own discomfiture.

An expert may be well posted and thoroughly truthful but may fail to make a good impression for want of attention to the matters suggested by Professor Mason's address. It was delivered before a non-medical assemblage, but the points it contained are worth the attention of those called as medical experts as well.

ON GOING FANTEE.

In Africa the negro, after being pulled some little way out of his savagery by the strenuous and ethical civilized master, shows a continual tendency to drop back into the primitive condition. The missionary labors for years to pound into the head of a black brother some notion of the Christian religion, thinks at last he has succeeded, when suddenly the man disappears and is found the chief actor in some barbaric and outrageous dance of superstition or of cannibalism. The white officer finds his trusted servant is not as usual on hand to perform his hitherto well done services. He too, for a longer or shorter time, has reverted to old habits that were temporarily held in abeyance by the will of the superior. In African lingo, these and all such lapses from a later and higher to an earlier and lower state are said to be "going fantee."

But it strikes us that it is not only the poor darkey that thus goes fantee, but that his civilized brother is occasionally guilty of the same custom. Indeed, do we not all feel the pull downward and backward? Do we not sometimes relapse secretly and pull up sharply again? Do we not have our private little fantee habits that logically belie our public virtues? At best, do we not keep ourselves in line by constant spurring of our better nature and tiresome attention to conscience and Mrs. Grundy? We all know of men who are as conscious of the disgrace as can be, and yet who seem incapable of resisting the impulse to go off once in three or six or twelve months and have "an old-fashioned drunk." It has been said that country merchants, despite the drummers, find it necessary to go to the city to buy their goods, and also to "see the sights," at least once or twice a year. In some rural places the conversion, sincere enough at the time, has with certain characters to be repeated every revival season. Even ladies, and great ones too—modern, we mean, not alone Neronian and Quatorzian, have been known to relapse in the peculiar feminine way from the most civilized ideals of conduct. This is probably the reason why so many preachers' sons go wrong, and also the sons of others who are constantly in the public eye. Their fathers are so watched that they have no chance to go fantee, and their sons by natural reaction and the law of compensation have to take upon themselves the disagreeable but easy vicarious task for the parents.

Nay, more! Is not the great scientific truth of atavism but an illustration of what may be called the more general law of going fantee? It is only tissue-fantee, one type or class, whilst fanteeism in its larger scope includes customs and habits, social, religious and ethical, of universal extent and spiritual significance. Telegony is therefore but one aspect of the law, and when the son of a virtu[illegible] and r[illegible]red father runs riot with all paternal [illegible] [illegible]tabilieit is a sort of spiritual telegony or fanteeism, just as well as when the highly bred animal is spoiled for breeding purposes by one marriage-error, or when the subsequent human husband finds the children of his own begetting are quite as much the heirs of his wife's first husband as they are his own. Lucifer would undoubtedly, in these scientific days, contend that the other angels were "too virtuous by half," and that his own fall was but an instance of angelic fanteeism on the part of the very proper ones who scapegoated their own sins upon him. He had to go fantee to save them all from little lapses, and Hades is where all the virtuous may temporarily go fantee before returning to civilized life, where "good form" and "the proper thing" may be resumed until the secret drag of concealed appetite can no longer be resisted.

And so, as perfect and virtuously superhuman as we undoubtedly are, we physicians are necessarily subject to the universal law; we also have our professional fanteeisms. For example, when we see in the daily papers accounts of Dr. Vanity's doings, his operations, cures, travels and appointments to hospital postions, we know of course what it means, and we sigh for the good man whose ethical habits are not continuously and uninterruptedly strong. When we find a doctor "laying pipes" and "wire-pulling" for a year with all the political arts of a CHOKER, FLAT or SWAY, to become the president of some medical organization, we wonder if this particular fanteeism is not an illustration of a very uniform tendency that will have its regular outbreaks in some sad form or other, either annually or more frequently. When we find a member of the profession certifying to the wondrous therapeutic effects of a nostrum; when we find a dozen "professors" employing a well-paid lobby to get State endowments for their "college" or "hospital;" when we find regulars defending sectarianism and consulting with quacks; when we find men who need no "antiquated code" to keep themselves ethical—when we note one or two of a hundred such symptoms in a patient, we perhaps shake our heads as to the prognosis, but we are in no sort of doubt as to the diagnosis, and we have no indecision as to what the treatment should be. Alas! that the consultant (the whole profession) will not consent to the somewhat drastic but necessary measures required for a speedy and permanent cure.

We might revert to one instance of a certain beginning, at least, wherein the American profession seems to be starting on a fanteëistic debauch. There are a few members of the ASSOCIATION who seem to look upon its annual meeting as an occasion for going fantee. Far be it from us to look with any sort of puritanic eyes upon innocent pleasures, even those of the stomach. But there is a huge difference between these and what some think admissible in the way of drinking and eating. It is becoming somewhat of a scandal among the laity that "these doctors are about as bad a lot as the rest of us." The writer has heard more than one such disgusted person sneer at the way some physicians behave at these meetings, and the way we carry on our "banquets" and "receptions." On the score of taste alone we should not fall into blunders of excess—we who are supposed to be the teachers of hygiene and the curers of belly-aches. There is much truth in the lay criticism. We allude to no recent events, but only speak in the most general way. The indebtedness of physicians for train-loads of things for "entertainment," to commercial advertisers, the giving of banquets to mobs of roaring, hustling, half tipsy people, the forcing of "hospitalities" upon overloaded stomachs and jaded senses—all this is as absurd and sickening as it is professionally wrong. Apart from the example it sets before a gaping lay world, it is doubly wrong because of the precedent it sets *en famille.* When the meeting takes place in ensuing years at smaller cities, or where the local profession is not so wealthy, it results in flagrant injustice to these local members, who by the vicious example are forced to pecuniary expense that is compelled and not voluntary, and which they can ill endure, or else the example of the previous meeting stings in their sensibilities or those of their thoughtless guests. There is at least one word of suggestion we would make as regards the entertainment at future meetings: Let there never be another "stand-up-feed." It is simply disgusting for people to fight for food and drink and then walk about and talk, choking down the things, spilling them over floors and dresses and littering rooms with soiled and broken crockery. Let whoever gives any sort of "entertainment" to his guests hereafter, for decency's sake, let him invite only the number his table will seat, and let these guests eat and drink as becomes ladies and gentlemen of civilized times!

Finally, not to be too serious in hot weather, we may allude to one wholly excusable, nay, advisable way of indulging inherited, half-outlived but still somewhat, though too little active tendencies and primitive habits of our nature. This is the play-instinct which has lately been alluded to in these columns. It is very literally a bit of atavism and reversion to a more barbaric way, but it is one, as we have said, quite admirable. We shall not be able to fall far or long at a time, as the exigencies of life prevent that. Indeed, our danger seems to be the reverse, and the privilege of taking a vacation is fast becoming a duty to be urged. No man has a moral or professional or social right to work so hard, and with such tragic things, as do we physicians for twelve months of the year. Perhaps the harmless method of atavism will prevent some other and far more regrettable method of "wasting time." If, as seems inevitable, we must all occasionally relapse, and moreover, if we always keep the strings too taut, they may snap, it is perhaps best that we choose the better rather than the worse forms of reversion. We have a choice even in such things as fanteeism. Death itself is but going fantee, and yet we may all more or less postpone this big "go" by wisdom and forethought. It should be a part of the "New Code" (if there is to be one) which every practitioner ought solemnly to swear to keep, that we would all take at least one month of play and rest. Leave the crowds, get to some quiet bit of nature, where man and his ills can not intrude, get on the old clothes, romp with the youngsters, read poetry, listen to the birds, and court your wives in good old primitive fashion. *Go fantee!*

TRAUMATIC RUPTURE OF THE HEART WITHOUT EXTERNAL LESION.

Wounds of the heart, while not actually rare, are by no means common. Occasionally recovery may follow such injury without surgical intervention, but as a rule death results. Recent experience in several recorded cases has shown that incised wounds of the heart are susceptible of successful surgical treatment, provided of course the lesion be not too extensive, the loss of blood not too large and the measures of relief are employed without undue delay. Contused and indirect wounds of the heart are even less common and naturally more difficult of recognition and correspondingly less amenable to surgical intervention. An interesting case of this sort, in which death took place suddenly a month after the reception of the injury has been placed on record by GROOM (*Lancet*, May 1, 1897, p. 1202). A lad 16 years old was caught between the shaft of a trap drawn by a runaway pony and some wooden railings. He was kept in bed for five days, but remained weak and unwell.

A month after the accident, while walking out of doors, the young man fell on the pathway, face downward, and was soon dead. Upon postmortem examination no sign whatever of injury to the superficial structures or the ribs was found. When, however, the pericardium was opened the sac was found to be filled with blood, some of which was clotted. On removal of this and turning the heart over without detaching it, a hole about the size of the end of a little finger through the middle of the posterior aspect of the left ventricle was discovered, the actual size of the rupture being about a third of an inch. On removing the heart and opening the ventricle the myocardium was found to be perfectly sound except at the spot mentioned. The hole was quite conical and bulging when the little finger was introduced, and the rupture external and consisting merely of the pericardial covering of the wall.

The conclusion is reached that the accident had caused a partial rupture of the inner portion of the wall of the left ventricle at a spot opposite to the point at which the shaft of the trap had pressed, and that the blood pressure had during the month intervening between the accident and death caused an aneurysmal bulging of the weakened part, its wall becoming thinner until ultimately it burst. The rupture viewed from the interior of the ventricle looked much like a bullet-hole.

CORRESPONDENCE.

The Treatment of Diabetes.

NEW YORK, Aug. 9, 1897.

To the Editor:—Pardon my further contribution to the subject of diabetes, now so wisely occupying attention in the JOURNAL.

I have no quarrel with Dr. Munson; he is too good a student and careful observer for me to do anything but welcome his opinions and observations no matter how I may differ from him. He knows things that I do not know and I believe I know some things that he does not know. The disease in question is very fatal and any light that can be thrown from any source should be welcome.

Carbonic acid, sulphydric acid and other paralyzing gases do directly act on the liver and help to increase the production of sugar in diabetes. Horses and cattle die suddenly from colic because of the self-same paralysis. Small boys sometimes die in a few hours from the colic produced by the fermentation of green apples which they have eaten. Cases of Bright's disease under treatment, whose urine has become entirely clear of albumin, casts and fatty epithelia, will have the same abnormal stigmata of that disease brought back by eating foods which ferment into these same paralyzing gases. A man under treatment for locomotor ataxia with great improvement in strength, gait and feelings is tempted into Delmonico's and given by a friend "a dinner which will not hurt him." This same dinner ferments and brings back all his pain, distress and troubles. Cases of consumption whose cough has ceased under treatment, will when they commence to eat the wrong food which ferments, invariably bring back the cough because of the irritation and paralysis of these same gases. A boy under treatment for partial paralysis of the lower extremities had improved so that he was able to locomote easily. A birthday party was given him and his fond mother loaded him up with ice-cream with the inevitable result of fermentation and paralysis of the lower extremities. I could go on much further. I know from my personal experience in the treatment of diabetes that foods that ferment do produce carbonic acid gas and other paralyzing gases and that they help the production of sugar. If a patient can eat sugar, potatoes, bread, starches of any kind, without this fermentation I believe their cases will go along all right.

One word as to beef dyspepsia. This results in the formation of sulphydric acid gas and is a troublesome thing to handle. I have seen but two cases of it in eleven years of study of chronic cases and have never seen it in the treatment of diabetes. If such should occur the treatment would be the stopping of solid beef, giving plenty of hot water, beef tea or the whites of eggs dropped in boiling water, as the condition of the patient demands. It is generally but a few days before the condition is cleared up, but this self-same paralyzing gas hinders the course of any treatment as much as the carbonic acid gas from the starchy and sugary fermentation.

I am sorry, exceedingly sorry, that the physiologists do not back me up. As one who earns his bread and butter in the treatment of disease, dependent not upon dead men's money which has endowed some profe[illegible] ar[illegible]itution of learning, I make one of the court of last appeal in matters medical, as the practitioner has to get at the truth of all theories and observations by his work with his patient.

My income would be much more precarious than a medical man's income generally is if I had to practice medicine on the dicta of physiologists. They do not give us light as to the management of chronic diseases; in fact I lay down the broad statement that the medical colleges all over this country neglect this important branch of the practice of medicine and that the volume of light which is now being thrown on such work comes not from pathologists or physiologists or works on practice of medicine but from practitioners' contributions in medical journals, the chief of which is the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.

As to alcoholic and acetic acid fermentation in the bowels, a study of morphology of the feces will show the alcoholic and acetic acid plants, and I have seen flour that has been raised into bread by the yeast, found in the feces of consumptives. As to the use of the term "morphology," as far as I know, Dr. Ephraim Cutter over twenty-five years ago was the first to employ the term in medical microscopy. The late Dr. Heintzmann then took it up and now a great many bacteriologists and some of the very recent students of the blood who are discovering the things which were worked out by Americans over thirty years ago are using this term morphology.

As to Victor Hugo and my reference to him, I simply call attention to my paper on "Tuberculosis and Vinegar" which will be published in the JOURNAL in due time, I hope, as part of a transaction of the Section on Physiology and Dietetics at the 1897 meeting. Robert Koch, no doubt, to a great many men is the beginning and end of all law and knowledge as to certain microscopic matters. Nevertheless there are others in the practice of medicine who did good work when Robert Koch was a small boy.

Dr. Munson doubts my diagnosis in the case of the young woman in 1888. As the patient was emaciated, suffered from great weakness, so that to move about she constantly had to urge herself or push herself, that she suffered from thirst and had peculiar feelings about the tongue, I thought that my diagnosis with the chemistry of the urine was right; it may have been wrong.

I do not believe in an exclusive beef diet as a panacea. There is nothing in medicine that is a panacea. If a beef diet is a panacea, perhaps I should not have buried my wife last Thanksgiving day though there were small cavities healed in both lungs which she had carried for seven years despite a fatal prognosis made in 1889 that she could live but three months. I believe, however, that if she had not lost her appetite three years ago, she would be living in fair health now, because a beef diet with but little other food prolonged her life and she died literally of heart failure.

I have had so many medical friends and enemies attack me on the ground that a meat diet did cause uric acid, coma and death, that I am very glad to find out that the profession is thinking differently.

Dr. Munson speaks of a case which suffered under a diet of meat, fish and eggs; I do not wonder. How any medical man would take a feeble case of diabetes and shove so much food on him, I can not understand. A diet of fish is not long tolerated; the yolks of eggs are a direct cause of cystinemia, as I have found in patient after patient, and cystin in the blood will produce rheumatism and neuralgias of the most excruciating types; oatmeal feeders also suffer with this. Parenthetically I might say that the best solvent of cystin is lemon juice.

Now, it is the bottom principle in feeding in chronic cases that the simpler you feed the more your patient improves. I generally put a case of diabetes on the broiled chopped beef with hot water one hour before meals, and on going to bed at night, and with drinks of beef tea between meals. I have invariably seen the sugar diminish under this regimen, and as soon as possible bring in other food, studying the case carefully.

Now, beef can be borne longer than any other single article of food: it digests easily, assimilates well and nourishes all tissues. I well recognize the fact that physiologists condemn it as an exclusive article of diet and I do not believe in putting any patient on one food unless absolutely necessary, but when patients have lived on beef alone, seasoned with pepper, salt, butter, Worcester sauce, horse-raddish or lemon-juice, as desired, with clear tea or coffee for from one month to two years, what am I going to do? Am I to give up all of my clinical evidence simply because physiologists say that the evidence does not exist, and patients can not live that length of time? Let me take other cases of chronic disease. A girl sick with epilepsy of several years duration could live on beef alone without seizures. She would be fed on it solely for several months, then solely on steamed whole wheat for a while. Either food alone caused no trouble; the two together would produce the explosions. After a while as she progressed she could eat them both together. Occasionally fits would come on her which we found were due to her stealing sugars or molasses, the same sugars and molasses fermenting (I am so sorry I again run *contra* to the *dicta* of the physiologists which state that there is no such thing as fermentation in the alimentary tract) and producing carbonic acid gas, this carbonic acid gas would start the seizures again. This case after two years of treatment and dieting, getting to the age of fifteen years, received some local treatment for amenorrhea and has remained cured for over six years.

In closing I want to call attention to one law in the treatment of chronic cases: unless a case is moribund, there is almost invariably an improvement under treatment; no matter if the case is so close to the grave that one doubts the wisdom of endeavoring to do anything, if, under careful management it is found that the nerve forces are not so wasted by the battle of life that there are some left to work upon or, if the nerve forces are nearly all run out, the patient has such a temperament that he will take on strength and will vegetate like a dog does when he is sick, there is a good-working chance of his recovery provided one can control finances and causes of worry; but the *contra* is often true; cases will make improvement for a while, but, despite the most careful management, the use of money and ample means, the best of nursing, the closest of study of everything impinging upon the patient, if that patient has wasted his nerve forces so far that they are practically gone and he has not the temperament to take on strength, he will surely go under and pass to his reward; hence, it is in the management of all these cases, Dr. Munson's, my own and others, we can not cure everybody, and we can not even temporarily relieve everybody and, therefore, our results can not not be based wholly on mortality lists.

Yours faithfully, JOHN A. CUTTER, M.D.

Increase of Diabetes.

MILTON, DEL., Aug. 12, 1897.

To the Editor:—In the JOURNAL of Aug. 7, 1897, I notice a communication from Dr. Ball of Philadelphia, Pa., calling the attention of the profession to the alarming increase of that dread and fatal disease, *diabetes*. One of his reasons assigned was the increased population of Jews in this country, and, he says, that the presentation of patients with that class of diseases to the hospitals far outnumbers that of any other nationality. His observation is without a doubt correct, but in this part of our country, where there is no other nationality except the native born, I find the same thing among us. So you see, that it is not confined to the Jews alone, but the gentile world as well. There is a cause for this. What may affect the Jews in their country and cause such troubles may not be a cause in this. At least I would not think the nationality had anything whatever to do with the disease. More than once I have advanced the idea that our modern way of living, the patent roller-made flour, which is deprived of all the coarser part of the flour, and must be of all or nearly all of the carbohydrates, which go largely into the nutritious element of the same. The low price of it puts it within reach of the poorest families, and they, too, indulge in what is called the best grade of flour, when, at the same time, it is the life nutrition, and when you intrude upon native with improved or adulterated foods I many times see that some of the organs and fluids of the body must suffer.

James A. Hopkins, M.D.

Medical Legislation.

Iowa City, Iowa, Aug. 15, 1897.

To the Editor:—At the meeting of the Iowa State Medical Society, at Des Moines in 1896, discussion was had concerning a project to unite the practitioners of the State into an association to "influence legislation." Nothing was done by the society but subsequently an association was organized and an effort made to secure a union for political purposes of all practicing medicine, including sectarians with various labels. Many declined to unite with the organization; some because they believed the discordant elements would prevent any useful work, and others because they believed that the attempt to organize a political club out of a profession would lead rather to adverse legislation than to any legislative reform of advantage. A circular is the first fruit that has emanated from the association; and it appears to the writer that the introduction of the profession to practical politics of this kind, is undesirable. The physician has the same rights and duties as other citizens, and experience has shown that the study of medicine does not lessen the capacity of a man to serve the people in legislation or administration. It would probably be better for the country if, as individuals, the members of the medical profession took the practical and active interest in politics that has been so noticeable among their *confrères* of France. The reproach, that such an association has been used to advance personal interests, can not help lessening its value as a protector of general interests. The association however is not an offshoot or a part of the State Medical Society of Iowa.

"Haller."

A Suggestion for the Next Meeting.

Boston, Aug. 18, 1897.

To the Editor:—Permit me to make a suggestion. If it be carried out I think it will add to the interest of our annual meetings. Some of us in the Association are engaged upon original work. This work can be presented to our brother members in two ways: by reading a paper about it, and (when it concerns something concrete) presenting the thing itself. The combination method at present employed could be improved on without infringing on the practical work of the Section. Instead of the momentary presentation of instruments, etc., in conjunction with the reading of a paper, would it not be well to have such devices and objects placed where the members could examine them at their leisure? Such an exhibit could be conveniently made in the rear of the hall where the Section meets, or in a reserved space in the usual exhibition hall. It would add nothing to the expense of the meeting, as a few tables is all that would be necessary for the purpose. Members of the Section having instruments, devices, X-ray pictures or other objects of practical interest could thus place them where their fellows could have access to them. If members had the opportunity to get a working knowledge of the new devices that are constantly being applied in the art of surgery, the practical utility of the Section would be increased. In time, perhaps, a surgeon who wished to keep abreast of his art could not afford to miss a meeting of the Association, not alone for what he could hear, but for what he could *see*. Trusting this suggestion will meet with consideration by interested members, I remain, respectfully,

Edward A. Tracy, M.D.

Infectious Disinfectors.

Groveland, Mass. Aug. 21, 1897.

To the Editor:—The following case was recently reported in the *Journal of Hygiene*, France: "A child suffering from a light attack of scarlatina is confined to his room for forty days, the room is disinfected by the board of health. Two days later the child presents undoubted symptoms of diphtheria—a patch on one tonsil. The physician in attendance does not doubt that the disinfectors brought this disease, as the child had seen no one but them and the physician who had himself not been exposed."

Such a theory seems hardly tenable. I have had cases in my own practice, of mixed infection, and others where diphtheria has followed scarlet fever, the patient ill at first with all the symptoms of scarlet fever and then with those of diphtheria. In none of these cases were cultures made demonstrating the presence of Klebs-Löffler bacilli. More recently I have had under my care a case where the symptoms were unmistakably those of scarlet fever supplemented by symptoms of true diphtheria. In this case cultures failed to show Klebs-Löffler bacilli, but supplied abundant evidence of streptococci. That there is a remarkable relationship between diphtheria and scarlet fever there can be no longer any doubt. Those who believe in this theory of unity of disease are finding considerable evidence to support their views.

W. Thornton Parker, M.D.

How the Defunct Osteopathy Bill was Passed by the Illinois Legislature.

Oneida, Ill., Aug. 20, 1897.

To the Editor:—I send you a *Journal of Osteopathy*. I know something of how they managed the late House at Springfield, which may be of interest, as I am well acquainted with our representative, Murdock. While the bill was being agitated I went to him and asked for his influence against it. He informed me that he was in favor of it, that one of the operators in the cult was at the capital demonstrating the treatment and one of the members who had sometime previously been laid up with an attack of rheumatism for six weeks, was taken suddenly one evening with a similar attack, and the osteopathic gentleman asked to be allowed to treat him just once and was granted the request. He at once proceeded to carry out the treatment in view of several of the other members. To use Mr. Murdock's expression, "he doubled his legs up and then pulled them out with a snap; thumped and pulled and doubled and rubbed and yanked. The patient the while yelled like a bull." After about half an hour of that he let his victim alone and by the next morning the man was as well as usual. Another patient was also exhibited. A man with dislocated wrist which the "doctors had failed to set or help," and he proceeded to at once replace it and let the man go without splint or bandage. To sum up, the man simply "pulled the leg" of the whole Illinois Legislature. Was it any wonder that the bill passed speedily on for the Governor's signature! But he showed himself a man with decision enough to refuse to sign it, thereby gaining the friendship of every reputable physician in the State and the ill will of a few cranks.

Yours for good, T. W. Davidson, M.D.

No Itinerant Quacks In Kentucky.

Executive Office State Board of Health
of Kentucky, Bowling Green, Aug. 7, 1897.

To the Editor:—After careful examination of the authorities Judge Thompson of Louisville has just handed down his opinion in our test case with the osteopaths. They had plenty of money and were ably defended, but after the proof was heard we never had any doubt as to the result. They are not only the most ignorant, but also the most unscrupulous lot of empirics with which we have yet had to contend in this State. Our law has now been in operation nearly four years. It has been tested upon every point and so far we have not failed to secure a conviction in each case tried. We convicted the Copeland people, the "K. & K.'s," and all other concerns of that kind doing business here, and are able to report that there is not now an itinerant or advertising doctor within the limits of the State. Very respectfully,

J. N. McCORMACK, M.D., Secretary.

[*Vide* JOURNAL, Aug. 14, 1897, pp. 351-352, Louisville column, for the text of this decision.]

Honorary Medical Degrees.

PHILADELPHIA, PA., Aug. 19, 1897.

To the Editor:—Apropos of the editorial in the JOURNAL of August 14 concerning the conferring of an honorary fellowship in the Royal College of Physicians on the Prince of Wales, it may be of interest to note that the first medical degree granted on this continent was an honorary one, bestowed on Daniel Turner of Connecticut by Yale College in 1720. As this was intended as a token of gratitude for Dr. Turner's liberal gifts to the college and not as a recognition of any particular fitness on his part to practice medicine, a wit of the time interpreted M.D. to signify *multum donavit.* Yours truly,

FRANCIS R. PACKARD, M.D.

PUBLIC HEALTH.

The Bacteriologic Laboratory of Princeton, N. J. is the recipient of a $3,000 appropriation from the State Legislature.

Disinfection of Bombay Mail.—The mail sacks from Bombay, per Cunard steamship *Servia,* from Liverpool, Eng., at New York, August 19, were transferred at quarantine for disinfection.

Ice Sources Must be Pure.—The Paterson (New Jersey) Health Board and the Police Department have united to enforce the law against persons dealing in ice cut from filthy ponds, rivers or lakes.

To Hurry Mortals Home.—The Health Commissioner of St. Louis has ordered an inspection of Chinese laundries. He fears that some may mouth-spray their work with tubercle bacilli, which being ironed into the clothing may cause contagion. Once these experts were in high esteem for washing infected clothes rejected by their timorous rivals.

Health in Michigan.—The report for July, 1897, as compared to that for June (*vide* JOURNAL, July 17, p. 186) shows consumption present at two places more; measles at 65 less; diphtheria at 26 less; scarlet fever at 19 less; whooping cough at 19 more; and typhoid fever at one place less. Compared with the July average for eleven years (1886-1897), measles was more prevalent; intermittent fever, cholera infantum, erysipelas, consumption, remittent fever and diarrhea less prevalent.

Health in Chicago.—The total number of deaths during July, 1897, was 2,275 or 1.44 per thousand against 1.52 per thousand in July, 1896. Of these deaths, 835 were persons under one year of age and 287 were between one and five years. The principal causes were: Infantile diarrhea, 413 deaths; diseases of nervous system, 231; consumption, 184; violence, 157; heart disease, 117; pneumonia, 79; cancer, 63; bronchitis, 48; diphtheria and membranous croup, 44; typhoid fever, 27.

Bovine Tuberculosis.—The State Board of Health of New York announces its belief in the efficacy of the tuberculin test for preventing the spread of cattle tuberculosis. Governor Black, however, vetoed an appropriation of $15,000 for the use of the Board in its investigations. The Saranac Board of Health intend to maintain a complete quarantine against the importation of untested cattle within the limits of their milk supply. As it is, nearly all the animals at this lake resort are native common stock and the more intelligent buyers of thoroughbred cattle refuse to accept purchases that do not pass the test in question. The State Board can do little more than merely approve these intentions.

The Duration of Infection in Whooping Cough.—Weill, who in 1894 expressed the opinion that whooping cough is contagious only during the premonitory catarrhal stage, has since put his opinion to the test (*Lyon Méd.*). On various occasions he permitted nearly one hundred young children who had not previously suffered from whooping cough to be associated in the same ward, for twenty days or more, with children suffering from the disease during the stage of whooping. In only one case was the disease contracted, and in this instance the patient from whom the infection was derived was in the very earliest period of the whooping stage. In three small epidemics, Weill was able to satisfy himself that infection was contracted from children who had not yet begun to whoop. He concludes that infection ceases very soon after the characteristic whoops commence, and that therefore in a family it is not the patient who is already whooping, but his brothers and sisters who have not previously had whooping cough, who ought to be isolated.—*Brit. Med. Journ.*

Smallpox Mortality in London, 1887-96.—The Asylum Board was first called upon to provide for the accommodation of smallpox patients at the end of 1870. During the ten years, 1871-80, they dealt with upward of 33,000 cases, all of which were treated in the town hospitals. The deaths in London in the ten years were 15,539, including 7,912 in 1871. In May, 1881, the "camp hospital" was opened at Darenth, and the system of removing cases of smallpox to the country thus initiated was gradually perfected, so that for many years all of the sufferers coming under the managers' care have been treated at extramural hospitals. During the ten years 1887-96, the number of cases admitted to the hospitals was 5,232. The deaths in London were 429 only, and of these 206 were registered in 1893, in which year 2,376 cases of smallpox were admitted to the managers' hospitals. Had the mortality during the ten years, 1887-96, been at the same rate as in the ten years, 1871-80, regard being had to increase of population, the deaths would have been not 429, but 18,752. The net gain in life saved during the ten years, therefore, was represented by 18,323 lives. In other words, had the average death rate from smallpox in the ten years 1871-80 continued throughout the ten years, 1887-96, 18,323 lives would have been sacrificed in addition to the 429 which were actually lost by death from this cause. This satisfactory result is admittedly due in a large measure, if not entirely, to the removal of nearly all cases of smallpox out of London.

Bacillus of Yellow Fever.—The superintendent of the Institute of Experimental Hygiene at Montevideo, J. Sanarelli, announces that he has succeeded in isolating a bacillus from the blood and internal tissues of yellow fever patients (See editorial in this issue.—Ed. JOURNAL), which produces the disease in animals inoculated with cultures of it, and also in man. The shape is that of a rod with rounded ends, growing in pairs or small groups in the cultures, developing on the usual media, with a specific appearance resembling a wax seal on a letter, when first developed ten to twelve hours in the oven and then the same length of time at the ordinary temperature. In the oven the culture develops iridescent and transparent, while at the ordinary temperature it forms shining, opaque drops like drops of milk. It is pathogenic for almost all animals, producing a cyclic disease lasting from five to twelve days, "analogous to the disease observed in man." He has also succeeded in isolating the toxin developed by the bacillus and producing the same disease with it as with the cultures direct. Two persons inoculated subcutaneously, and three with intravenous injections of comparatively feeble doses of the filtered cultures, developed the typical picture of yellow fever, with all its clinical and anatomic manifestations. He is now engaged in serotherapeutic experiments, which already promise well.—*Semaine Méd.*, July 7.

A Decrease in Immigration.—In the entire period of federal supervision which dates from 1882, 7,432,016 immigrants have entered the United States. The arrivals of Russian Jews for the last year numbered 22,750, as against 45,137 for the fiscal year ended June 30, 1896. Italy furnished the greatest number of immigrants, 54,431, a decrease of 8,629 from last year. The cause of the heavy Italian immigration of 1896 was believed to be the war with Abysinnia, but the figures for the last year are not abnormal, having been exceeded by several years of the period. Since 1882 there has been a large and steady decrease in German immigration; in 1882, 250,630 people entered the United States from that country, while in 1896 only 22,533 arrived. It will be seen that the number of German immigrants in the first year of Government supervision exceeded the immigration from all countries in the last year. Immigration from Austria-Hungary decreased from 55,103 in 1896 to 33,031 in 1897. The decrease from other countries is as follows: England, 19,492 in 1896 to 9,974 in 1897; Sweden, 21,137 to 13,144; Norway, 8,155 to 5,842; Ireland, 40,262 to 28,421. By way of commentary it may be said that much encouragement has been disallowed by our own government as against the false representations of steamship lines, whose aim was for the profits of the steerage. Labor was not actually in demand and depleted purses left the victims of delusion stranded in the larger seaports. Fortunately neither crime nor disease became rampant because of the counteracting forces of dispersion and the lessons of governmental indifference taught from very infancy.

The French Academy of Medicine and the Prevention of Phosphorus Disease.—The important part taken by the French Academy, acting as an advisory department of the government, in this branch of disease prevention should not be overlooked. In that country the manufacture of matches is a state monopoly, and in view of the numerous cases of sickness and criticisms in the press, the authorities have requested the Academy to frame new regulations for the management of the factories. In the discussion that ensued it was evident that medical opinions were divided. One party advised that white phosphorus should no longer be used, as has been done in Belgium; others, however, thought it would be sufficient from a sanitary point of view to alter the arrangement of the workshops so as to obtain thorough ventilation, while refusing work to all who had not good teeth. The workers must be under strict medical supervision, and, as far as possible, machinery should be constructed so as to allow the whole process of manufacture to go on under glass, the workmen being protected from the poisonous fumes. In two factories, viz., at Algiers and Aix, there has not been a case of phosphorus poisoning for twelve years owing to the strict hygienic rules which have been in force. The cases which have so excited public opinion occurred at Aubervilliers, a suburb of Paris, in a very old factory which it is impossible to put into a sanitary condition and which ought to be pulled down, as to make it really healthy would cost more money than to build a new one. The real fact is that the workmen of Paris object to the introduction of machinery for the safe manufacture of matches with white phosphorus—that is to say, under glass—for in that case far fewer hands would be wanted, and they therefore demand the use of red phosphorus, to work in which necessitates a larger staff. This is the reason why, in Belgium where the manufacture of matches is free to anyone the workmen object to red phosphorus, and why in France the State, which panders to the political influence of the workers, is ready to satisfy them on this question, despite the increased expense. Matches made with red phosphorus are not so good as the others, for they are more difficult to light, the wood is very brittle and often breaks and the composition for tipping them demands the use of explosive materials which, like poisoning, constitute a serious source of danger. The Academy has agreed to the following answer being sent to the Minister: 1. It is necessary to put a stop to the unhealthy conditions which exist in many of the match factories of France. 2. The suppression of the use of white phosphorus is the only certain way of insuring health to the workers in this manufacture. 3. The employment of perfected automatic machinery is a costly matter and carries with it the condition that all dangerous operations should be done under glass. 4. Until these recommendations can be carried out as a whole the present condition of unhealthfulness can be reduced by careful sanitary supervision.

NECROLOGY.

CORNELIUS KOLLOCK, M.D., Cheraw, S. C., August 16, aged 73 years. Dr. Kollock was graduated from Brown University in 1845, and from the medical department of the University of Pennsylvania in 1848. He then studied two years in Paris under Malgaigne, Cazeaux, Record, Velpeau, Siebel and other French surgeons of eminence. He was president of the Pee-Dee Medical Society for many years; of the South Carolina Medical Association in 1887; was elected vice-president of the American Gynecological Society in 1892, and in 1894 was president of the Southern Surgical and Gynecological Association.

Dr. MORVAN has died at Lanniles, France, aged 73 years. In 1871 he was a member of the legislative assembly, but had for a long time given up politics for the sake of scientific work. He was the first to describe the group of clinical symptoms known as "Morvan's disease," which he considered to be a form of syringomyelia. Since then Dr. Zambaco-Pacha of Constantinople, having traveled in Brittany, where Dr. Morvan studied the disease and where it is very common, came to the conclusion that it is an abortive form of leprosy. Dr. Morvan was a corresponding member of the Academy of Medicine.

JOHN J. H. LOVE, M.D. Draft of a minute adopted at the meeting of the visiting staff of the Mountain-Side Hospital Aug. 16, 1897, in reference to the death of Dr. John J. H. Love (*Vide* JOURNAL Aug. 7, 1897, p. 297).

No words can express the loss which the Mountain-Side Hospital has sustained in the death of Dr. Love, nor is it possible to so construe language as to give the measure of our personal loss in the death of our beloved leader. Filled with the courage and self-sacrifice that are born of high purpose and unselfish broad mindedness, and always willing to prefer the well-being of others to his own, he gave freely of his time and substance to the hospital. Its good name was as dear to him as his personal honor, and from his clear and comprehensive mind came most of the suggestions by the adoption of which the enterprise has been successfully carried on. Without Dr. Love it would have failed, with him it has achieved an enviable measure of success and usefulness. We can no longer enjoy his friendship, his guidance, his counsel nor his sympathy, but we have the brilliant example of his noble life, and of his devotion to the best interests of this hospital.

RICHARD C. NEWTON,
E. M. WARD, } *Committee.*
H. B. WHITEHORNE.

JAMES COZAD, M.D., Reynolds, Ill., August 15, aged 61 years.—Adam B. Finney, M. D., Washington, D. C., August 9, aged 61 years.—Cornelius A. Groot, M.D., Auburn, N.Y., August 12. E. M. McPheron, M.D., Janesville, Wis., August 12, aged 25 years.—John Townsend, M.D., Holgate, Ohio, August 13. Dr. Dewindt of Alost, president of the Belgian Medical Association.—Dr. O. Boer, co-laborer with Koch.

SOCIETY NEWS.

Election of Officers.—At the meeting of the American Association of Gynecologists and Obstetricians, just closed at Niagara Falls, N.Y., the following officers were elected: President, Dr. Charles A. L. Reed of Cincinnati; vice-presidents, Dr. Richard Douglass of Nashville, Tenn., and Dr. Walter B. Dorsett of St. Louis; secretary, Dr. William Warren Potter of Buffalo; treasurer, Dr. X. O. Werder of Pittsburg. The next meeting will be held at Pittsburg, Pa., Sept. 20, 21 and 22, 1898.

The Second Congress of Hydrology in Italy was held at Sangemini, and was principally devoted to exploiting the qualities of the famous mineral waters there, and its exquisite scenery. The waters are "acidulo-bicarbonate-calcic," and the establishment is managed according to the latest scientific theories, under the supervision of Olivieri, Santucci and Violati. The inauguration of a "Cure tax," like those of Germany, was discussed and approved. Dr. Fabbri proposed to found a large sanatorium at the Falls of Terni, where the climate and scenery are equally superb. He invited co-operation to render the project a success. Carlinfanti reported the results of his investigations on the solubility of uric acid in acidulo-alkalin waters, which proved that they will dissolve in nine hours five times more uric acid than pure water.—*Gaz. d. Osp. e d. Clin.*, July 18.

MISCELLANY.

The Boston Medical Library has been enriched by the collections of the late Drs. Edward Wigglesworth of Boston and William G. Wheeler of Chelsea, both of whom were industrious bibliophiles.

The Contractions of the Stomach studied with the Roentgen ray have resulted in establishing the fact that in the human stomach, like that of the frog and the dog, the larger part serves as the receptacle for the food, while the smaller prepyloric part is the motor organ of the stomach.—*Semaine Méd.*, July 28.

Progressive Osteoporosis.—Debove distinguishes by this term the form of osteomalacia in which the bones do not become softened but merely grow more and more porous, leading to progressive deformity and final death from thoracic accidents. The *Bulletin de l'Acad. de Méd.*, July 20, contains three typical observations.

Almshouse Amenities.—An Albany (N. Y.) dispatch to the New York *Herald* of August 11 reports that at the almshouse in North Hempstead, Queens County, one woman gave birth to four children while she was in the institution, and another woman had one child born under the same circumstances. The women are feeble minded and have been allowed to go out at intervals and return when they pleased. The State Board of Charities has ordered them sent to the Newark Asylum, where they can not have liberty. The five children have become county charges.

Admissible Evidence of Previous Condition.—A physician who had treated the plaintiff some three or four years before she was injured by an accident, and who had seen her somewhere from six months to two years prior to the happening of the accident, should be allowed to testify as to her physical condition prior to the happening of the accident. So holds the appellate division of the supreme court of New York, in Loudoun v. Eighth Avenue Railroad Company. The testimony, it says, being as to knowledge obtained in regard to the party's condition within a period of from six months to two years prior to the happening of the accident, was not so remote but that it formed some basis for comparison between her condition then and that which he exhibited at the time of the examination before the trial.

The Celluloid Bandage Casts proposed as a substitute for plaster casts, made by dissolving scraps of celluloid in acetone and spreading it on mull (*vide* JOURNAL, p. 437, Vol. xxvii), are highly recommended by Maass of Berlin, who has applied more than a hundred during the last ten months and is convinced of their superiority to the usual cast. They are extremely light, elastic, clean and imperishable, not affected by heat, perspiration nor pus, so solid that no steel supports are required, while they can be made with celluloid hinges when desired for articulations. The technique is very simple; any physician can make them without the assistance of an expert, and the danger from fire is slight; it is impossible for the cast to explode. The only disadvantages are that they take longer to harden, 8 to 12 hours (usually having to be made over a cast), and are a little more expensive on account of the acetone.—*Deutsche Med. Woch.*, July 29.

A Question of Values.—"I suppose," remarked the sarcastic house wife, "that in the course of time ice will be worth as much as diamonds."

"Well," replied the ice man, reflectively, "diamonds are pretty good in their way, but you can not rely on their melting down so as to keep up a steady demand."—*Washington Star.*

Death by Poison.—A man, feeling slightly ill, went into a drug store in Detroit, and asked the proprietor to give him something to relieve the pain, and the proprietor, by mistake, gave him some aqua ammonia. It burned his mouth very severely, but he lived some fifteen days thereafter, when he died from the effects of the potion taken. The supreme court of Michigan holds that, under the circumstances, it was "death by poison," in contradistinction to the contention that it was a death from shock experienced when it was discovered that something wrong had been taken. (Early v. Standard Life and Accident Insurance Company.) The fact that the poison was accidentally administered, supposing it to be another substance, the court further holds could not take the case out of, but rather brought it within the exception in a policy of accident insurance excepting from its provisions death from poison.

Some General Principles that Should Govern Operations for Otitic Brain Disease.—Green (*Boston Medical and Surgical Journal*, Aug. 12, 1897, p. 145) includes among otitic brain diseases external pachymeningitis with extradural abscess, leptomeningitis or arachnitis, encephalitis or brain abscess, and phlebitis and thrombosis of the sinuses and the jugular vein; all caused by infections from the ear, the microbes being the same varieties as are found in the suppurating ear cavities, chiefly streptococci, staphylococci and pneumococci. In cases of otitic brain disease early operation is advisable, but an early exact diagnosis is often impossible. The chances are seventy-nine in a hundred that a fistula through the bone from the ear will lead directly to the brain abscess disease. The infected ear requires operation in any case, and this operation can be combined with an exploration for the bony fistula and the recognition and treatment of the brain disease.

The Memory of the Very Aged.—By reference to the newspaper statements of incidents in the lives of our still living centenarians, General Washington's nurse seems to have entirely vanished. One derelict, however, claims to have chatted with the first President when she must have been only six years old. As the reciter's years were made to fit the incident, in a medico-legal way, we should not hasten to gainsay it. Still the deduction is that the happening, provided it did occur, was of the nature of a faint impression developed by the iterations of others through a series of years. Personal vanity no doubt painted as usual with its yellow colors and not without its best art. How curious that the distance of four-score years lends both a haziness as well as an enchantment to the declining years! May we not add how fragmentary is the mosaic of all knowledge! Still, in the present instance, with all the fantastic tricks of the reigning psychology, we shall not pretend to make an allegation of falsehood. Let the poor subjects of an extravagant longevity hug their delusions of a golden age to them gone forever, for no doubt they were excused from the grosser sins, or their lives would not have been so indefinitely prolonged.

Hospitals.

By the will of the late William Lewis Dayton the Mercer Hospital, Trenton, N. J., received $2,000.

The West Pennsylvania Hospital, Pittsburg, Pa., is to be enlarged by a new wing 145 by 55 feet, constructed of brick and four stories in height.

Ground will be broken in September for a hospital at Jamaica, Long Island, N. Y. The plans call for a substantial modern structure, extremely plain in its architectural lines. The building will have open plumbing throughout, special attention being given to the fixtures in the operating rooms and ventilating devices.

Societies.

The following meetings of societies are noted.

Indiana—Henry County Medical Society, Newcastle, Aug. 12.

New York—American Association of Gynecologists and Obstetricians, Niagara Falls, August 17-20. Cayuga County Medical Society, Auburn, August 13.

Pennsylvania—Berks County Medical Society, Reading, August 10. Bradford and Susquehanna County Medical Society, Lake Carey, August 10.

Texas—Lone Star Medical Association, composed of colored physicians, Houston, August 14. Texas Association of Railway Surgeons, Galveston, August 10.

Virginia—The twenty-eighth annual session of the Medical Society of Virginia will be held at Hot Springs, August 31 to September 2.

Wisconsin—Ashland County Medical Society, Ashland, August 12.

Louisville.

Lexington Insane Asylum. Dr. E. M. Wiley of Harrodsburg, has been appointed by the Governor as superintendent of the Eastern Kentucky Insane Asylum at Lexington in the place of Dr. Scott. Dr. Wiley's appointment has met with general approval. He was born in Jefferson County, Ind., forty seven years ago, is a graduate in medicine from one of the schools of Indianapolis, and has for several years been the surgeon of the Southern Railway at Harrodsburg. Dr. John L. Long of Louisville has been appointed as first assistant physician. Dr. Long made an enviable record a number of years ago as superintendent of the Louisville City Hospital, which position he held for several years, and he was prominently mentioned and endorsed for the position of superintendent of the Central Kentucky Insane Asylum at Lakeland in the place of Dr. McNary deceased, to which place Dr. Goslee, the former first assistant was finally appointed.

School of Reform. A year or so ago, as recorded in these columns, the State Legislature passed a law appropriating $100,000 for the purpose of establishing two reform schools for youthful criminals. Since that time the commissioners appointed by the Governor have been trying to decide upon a location, and at a meeting held this week in this city it was decided to locate one of the institutions in Fayette County near Lexington, if the offer made some time ago for a contribution of $5,000 from the city and $8,000 from the county is held good. At present both sexes will be received at this institution, though it is ultimately expected to have separate institutions. The commissioners are authorized to borrow the necessary funds by special act of legislature. A farm of not less than 100 acres will be selected at once to be approved by the commission and work will be begun immediately. The limit of the cost of the institution will be $50,000.

Muldraugh Hill Medical Society. This society, which is composed of the medical men of Hardin, Hart, Larue, Grayson, Meade, Bullitt and Jefferson Counties, has just concluded its second semi-annual meeting at Elizabethtown with Dr. Jerome Smith of Larue, president, in the chair. The next meeting will be held in the same place in December.

Pension Examiners. At the last meeting of the two boards, the new one appointed by President McKinley and the Democratic Board which claims that it is covered by the Civil Service rules, it was ascertained that all applicants for examination held instructions from the commissioner of pensions at Washington, to appear before the new board for examination. The old board will appeal to the Civil Service Commission for a ruling on the subject. The old board is composed of Drs. Ewing Marshall, T. P. Satterwhite and M. K. Allen.

Dr. E. W. Logan, who has been prominent in local politics for several years, has sold out and will go to Oregon for the winter, when he will leave in the early spring for Klondike and the Alaskan gold fields.

The University of California and the Homeopaths.—We publish below the recent correspondence in the matter of the petition for recognition of the homeopathic sect in the medical faculty of the university. The tenets of Hahnemann long since died in Europe, the place of its birth, but in the fertile soil of the newer, freer America, ill weeds grow apace.

PETITION OF THE HOMEOPATHS.

To the Honorable Board of Regents of the University of California.

Gentlemen: We, the undersigned directors and stockholders of the Hahnemann Hospital College of San Francisco, having been appointed a special committee by the board of directors of the said institution to present to your honorable body a petition praying for the affiliation of the Hahnemann Hospital College of San Francisco with the University of California, thereby forming a homeopathic department of the university, do hereby ask that such prayer be granted. The Hahnemann Hospital College of San Francisco was incorporated in 1881 and threw open its doors to students in June, 1884, since which time it has given a regular course of lectures each year in all branches of medicine and surgery. There have been graduated from said institution 125 students, and there are at present twenty-seven students in the various classes. The college has always demanded a high standard of education from its graduates. It required three full years of study in the college from its beginning and was with the medical department of the University of California, the first to demand a full four years' course of study in the college, as a compulsory requirement for graduation. The college, though not endowed, is wholly free from debt. There are in the State of California in actual practice today about twenty-three hundred licensed physicians of all schools, of which number, by actual count, 465 are of the homeopathic school, about one-fifth of the whole number. As the patrons of homeopathy are among the well-to-do class of citizens and not so much among the masses as the patrons of other schools of practice, it is undoubtedly a fact that such patrons pay at least one-third of the taxes of the State. Because we believe it to be for the best interests for the Hahnemann Hospital College of San Francisco, for homeopathy on the Pacific coast, for the large number of citizens and taxpayers of this State who do now or who may in the future employ homeopathic physicians, that the said college should be under the protection of the State University, and also because we believe it to be for the best interests of the University of California, as a great university, that there be a homeopathic department connected with it, we do therefore pray that the Hahnemann Hospital College of San Francisco may become affiliated with the University of California.

REJOINDER OF THE MEDICAL FACULTY.

To the Regents of the University of California:—A petition has been placed before your honorable body by the Homeopathic School of Medicine of this city praying that they be made an affiliated college of the University of California, which would therefore constitute them a teaching body of the University of California. There is, however, already a Medical Department of the University of California, which has always discharged its duties faithfully and unselfishly, working zealously for the honor of the university and for the advancement of medical knowledge. The present medical department feels that it would be an unjust criticism of their work if another faculty were appointed and tantamount to an assertion by the regents that the work of the present faculty was incomplete from a university standpoint. If such an opinion be held by the regents then it is only fair that they should first apprise the present faculty of its deficiencies so that an attempt may be made if found necessary to rectify them. But the present faculty of medicine does not believe that the regents have any intention to make such a criticism of its present faculty of medicine. They believe that the regents, in lending an ear to the petition of the homeopathic school of medicine, are simply wishful to find if it might be for the greater advancement of the university to take in a school which asserts itself to be possessed of a more enlightened and successful mode of treatment than any other so-called school or collection of individuals now practicing medicine. The following facts would seem, however, to indicate that their boast of having a superior mode of treatment or a more advanced knowlege of medicine than the regular school of medicine is not well founded: Homeopathy began in 1810 with the publication by Hahnemann of his "Organon der rationellen Heilkunde." From then till now, a period of eighty-seven years, all scientific advance has found a ready ear and quick appreciation in all the civilized countries. Let us now examine carefully what respect and appreciation the homeopaths have been able to win either from the scientific world or from the general public. They are not recognized either in the army, navy or civil service of any government in the world, including our own. They are recognized by no institution of learning in any foreign country, and by only two institutions of learning in our own country, viz,, Ann Arbor and the University of Iowa. Johns Hopkins University, for example, that particularly prides itself on its work of investigation, has not a single homeopath on its medical faculty. There are very few homeopaths in Germany, the birthplace of the founder, and no university there teaches homeopathy, but the verdict of the scientific world has been endorsed by the general public in so far that all steamships, all railroads and all life insurance companies choose almost invariably the medical services of the regular profession.

During all the eighty-seven years that the homeopaths have been in existence we can not recall a single instance of a scientific discovery in the field of medicine by one of their number, nor the fostering of scientific thought in one of their schools. The discovery of the sleep producing effect of ether and chloroform were made by regular medical men, working in regular medical schools. Lister, the originator of antisepsis in surgery from which the whole vast progress of modern surgery dates, is a regular physician and surgeon. Koch, the discoverer of the *cause of consumption and of cholera, is a regular medical practitioner*, working in a regular school. Pasteur, a chemist, worked under the auspices of a regular medical school. The discovery of the germ causing typhoid fever, and in fact the whole system of modern sanitary medicine and quarantine measures have developed under the influence of the regular school of medicine. The serum treatment for diphtheria by Behring was instituted in a regular working in the University of Berlin, a regular medical school. The great medical events of our own city have been carried out by members of the regular profession. The curing of an aneurysm of the abdominal aorta by Jno. F. Morse, the perfecting of the crushing operation for stone of the bladder by Chismon and the finding of a rare form of skin disease close to a parasite called a psorosperm by Rixford have all been done by members of the regular profession. Both Professor Le Conte and President Jordan, two of the most distinguished leaders of thought in the natural sciences in this country, are graduates from regular medical colleges and although not engaged in the practice of medicine yet serve to show that an education in a regular medical college does not dull a man's intellect or render him illiberal. This list of discoveries, investigators and educators, proves, if it proves anything, that the regular medical profession is not inimical to progress. It is therefore not likely, if homeopathy were in the line of progress, that it would meet with opposition from such an enlightened body of men as compose the regular medical school. And furthermore, it is to be said that not one of the propositions put forward by the homeopathic medical school has advanced out of the realm of theory into that of actually realized fact, and this after a trial of eighty-seven years in an age of scientific progress.

THE PUBLIC SERVICES.

Army Changes. *Official List of Changes in the Stations and duties* of officers serving in the Medical Department, U. S. Army, from August 14 to 20, 1897.

Col. Dallas Bache, Asst. Surgeon-General (Chief Surgeon, Hdqrs. Dept. of the Platte), leave of absence granted is extended one month.

Capt. Henry A. Shaw, Asst. Surgeon (Ft. Snelling, Minn.), *is granted* leave of absence for one month, with permission to apply for an extension of one month.

First Lieut. Charles *Lynch*. Asst. Surgeon (Ft. Robinson, Neb.), leave of absence granted is extended one month.

Capt. Henry S. T. Harris. Asst. Surgeon, is granted leave of absence for one month, to take effect upon his relief from duty at Ft. Preble, Maine.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 21, 1897.

Asst. Surgeon F. L. Pleadwell. *detached from the* "Texas" August 17 and ordered to the "*Nashville*" August 19.

Asst. Surgeon W. M. Wheeler, detached from the "Oregon" August 23 and ordered to the Mare Island *navy yard for duty in connection* with the "Marietta."

Asst. Surgeon *D. H. Morgan, detached* from the "Monongahela" and ordered to the "Cincinnati."

Surgeon A. G. Cabell, detached from the "Monongahela," ordered home and be ready for sea.

CHANGE OF ADDRESS.

Armstrong, W. S., from 12 Vine St. to St. Charles and Montrose Boul., Chicago.

Dunn, Sherwood, from Los Angeles to Hotel Coronado, Coronado, Cal.

Davis, J. S., *from Ocean Springs, Miss., to Charlottesville, Va.*

Eastwood, A. Y., from Cleburne, Texas, to Marsdin, I. T.

Eichberg, J. H., from 18 E. 9th to N. E. cor. 7th and Race Sts., Cincinnati, Ohio.

Fitzpatrick, T. V., from 186 W. 8th St. to 32 Garfield Place, Cincinnati, Ohio.

Fisk, S. A., from St. Luke's Hospital to 37 18th Av., Denver, Colo.

Hall, R. B., Dr., from 154 W. 8th St. to Berkshire Bldg., Cincinnati, Ohio.

Hefflebower, R. C., *from 628 Elm to N. E. cor. 7th and Elm Sts.*, Cincinnati, Ohio.

Owen, W. E., from Fox Lake, Wis., to Williamsburg, Iowa.

Pearce, C. T., from 20 W. 7th St. to N. E. cor. 7th and Race, Cincinnati, Ohio.

Reed, C. A. L., Dr., from 311 Elm St. to N. E. cor. 7th and Race, Cincinnati, Ohio.

Stewart, R. W., Dr., from 25 E. 8th St. to Ortiz Bldg., Cincinnati, Ohio.

Schultz E. T., from Reedsburg to Milwaukee Hospital, Milwaukee, Wis.

Semple, John M., from Medical Lake to Review Bldg., Spokane, Wash.

Shadle, J. E., Dr., from Endicott Bldg. to Lowry Arcade Bldg., St. Paul, Minn.

Taylor, H. S., Dr., from 590 Endicott Bldg. to Lowry Arcade Bldg., St. Paul, Minn.

Wiley, E. M., from Harrodsburg to Lexington, Ky.

ADDRESS.

CLASSIFICATION AND SURGICAL TREATMENT OF ACUTE PERITONITIS.

Read by invitation in the General Session of the International Medical Congress, at Moscow, Russia, Aug. 20, 1897.

BY N. SENN, M.D., Ph.D., LL.D.
CHICAGO, ILL.

An intelligent and systematic discussion of the treatment of acute peritonitis must necessarily be based on a rational classification. A great deal that has been said and written on this subject, from the distant past until the present time, is worthless from a scientific as well as a practical standpoint, owing to a lack of a proper classification. The ordinary terms used to designate the different forms of peritonitis are differently interpreted and applied by pathologists as well as clinicians. Acute inflammation of the peritoneum is produced by so many different causes and assumes such varied clinical aspects, that it is extremely difficult to formulate a uniform and satisfactory classification. A discussion of the etiology, differential diagnosis, prognosis and treatment of acute peritonitis, except upon the basis of a clear and comprehensive classification, is fruitless, misleading and usually results in the deduction of erroneous and often dangerous conclusions. The classification should include the anatomy, pathology and etiology of the disease to be of value in rendering a correct diagnosis, a reliable prognosis, and in enabling the physician and surgeon to advise and apply effective therapeutic measures. It is especially important in the discussion of the surgical treatment of peritonitis, before an audience composed of physicians and surgeons, to make a clear distinction between the different clinical forms of peritonitis with a view of pointing out the limitation of purely medical treatment and the legitimate scope of surgical intervention. The clinical classification which I here suggest appears to cover the ground fairly well, but would be incomplete without an exemplification from other standpoints, and for this reason I have prepared the following:

SYLLABUS OF CLASSIFICATION OF ACUTE PERITONITIS.

Anatomic.—Ectoperitonitis, endoperitonitis, parietal peritonitis, visceral peritonitis, mesenteritis, epiploitis, perigastritis, peri-enteritis, perityphlitis, peri-appendicitis, pericolitis, perihepatitis, perisplenitis, pericystitis (urinary and gall bladder), perimetritis, perisalpingitis, peri-oöphoritis, pelvic peritonitis, diaphragmatic peritonitis.

Etiologic.—Traumatic peritonitis, idiopathic peritonitis, perforative peritonitis, metastatic peritonitis, puerperal peritonitis, peritonitis infantum, fetal and intra-uterine peritonitis, peritonitis neonatorum.

Pathologic.—Diffuse septic peritonitis, putrid peritonitis, hemorrhagic peritonitis, suppurative peritonitis, serous peritonitis, fibrinoplastic peritonitis.

Bacteriologic.—Streptococcus infection, staphylococcus infection, pneumococcus infection, bacillus coli communis infection, gonococcus infection, tubercular infection.

Clinical.—Ectoperitonitis, general septic peritonitis, perforative peritonitis, circumscribed peritonitis, hematogenous peritonitis, visceral peritonitis (same as anatomic), pelvic peritonitis, puerperal peritonitis, subdiaphragmatic peritonitis.

1. *Ectoperitonitis.*—An inflammation of the attached side of the peritoneum is called ectoperitonitis. As compared with inflammation of the serous surface, this inflammation of the subendothelial vascular connective tissue is characterized clinically and pathologically by intrinsic tendencies to limitations of the inflammatory process. The mechanical and anatomic conditions for diffusion of the infection are less favorable than when the free surface of the membrane is affected. Ectoperitonitis, however, in certain localities may become quite diffuse, as, for instance, when the cavum Retzii (William Gruber), or the retroperitoneal space on either side of the spinal column are the seat of a suppurative inflammation. In the latter locality a paranephric or spondylitic abscess is often the cause of an extended ectoperitonitis, the extent of the disease corresponding with the size of the subperitoneal abscess. In infected wounds of any part of the abdominal wall in which the peritoneum is exposed, but not perforated, the primary ectoperitonitis is occasionally followed by the extension of the infection to the serous surface through the lymphatics, or the direct extension of the infective process through the tissues until it reaches the endothelial lining. Peritonitis of a visceral origin is always preceded by ectoperitonitis, whether the infection reaches the peritoneal cavity through a perforation or by progressive extension of the infection from the primary focus through the tissues until it reaches the free peritoneal surface. The surgical treatment of an ectoperitonitic suppurating focus is curative and prophylactic. The prophylaxis consists in the prevention of rupture of the abscess contents into the free peritoneal cavity by an extraperitoneal incision and drainage, which ordinarily results in healing of the abscess cavity and a permanent cure. Paranephric abscesses should be treated by lumbar incision and drainage; tubercular spondylitic abscesses without fistula formation, by tapping and iodoformization; pelvic abscesses in the female, whenever practicable, by vaginal incision and drainage. If the abscess is not within reach by the vaginal route, an incision is made through the abdominal wall directly over the abscess and in the absence of adhesions the parietal peritoneum is sutured to the surface of the abscess wall and the abscess incised and drained at once, or the incision is tamponed with iodoform gauze and the abscess opened and drained a few days later after the peritoneal cavity has been more thoroughly excluded by the formation of firm adhesions.

Suppurative inflammation of the loose connective tissue in the cavum Retzii leads often to extensive ectoperitonitis, occasionally to perforation into the peritoneal cavity, septic peritonitis and death. Leusser ("Ueber das Cavum Retzii [illegible] die [illegible]annten prävesicalen Abscesse," [illegible] [illegible]rgie, No. 32, 1885) has collected forty-six such cases and has made some important investigations concerning the structure and arrangement of the tissues in the prevesical space in reference to the directions in which the pus will burrow when this space is the seat of a phlegmonous inflammation. He found that the loose connective tissue between the peritoneum and the abdominal muscles is divided into two layers by a plane of fascia which is inserted into the upper border of the symphysis. An abscess in this region may therefore be submuscular or prevesical; the former occupies the space between the fascia and the muscles and assumes an ovate outline with the pointed extremity of the swelling directed downward; an abscess behind the fascia, a true prevesical abscess, resembles in outline the disturbed bladder. The prevesical abscess can be reached by rectal and vaginal examination and disturbs the function of the bladder. The indications for prompt surgical interference are particularly urgent when the abscess is deep, subperitoneal, as it is in such cases where the peritoneum is extensively involved, and the danger of extensive burrowing of the pus is greatest, and perforation into the peritoneal cavity most frequently takes place. The proper treatment of an abscess in the cavum Retzii is an early and free incision made in the same manner and with the same care as in operations for stone in the bladder by the suprapubic route.

2. *General septic peritonitis.*—The greatest confusion still prevails among pathologists, physicians and surgeons in reference to what is meant by general septic peritonitis, more particularly as to the distinction between septic and suppurative peritonitis. I understand by a general septic peritonitis an inflammation of the entire peritoneal sac with the serous covering of all abdominal organs, which, as a rule, proves fatal from progressive intoxication before sufficient time has elapsed for the formation of pus or any considerable transudate, or before any marked macroscopic tissue changes have occurred. It is the result of the most virulent infection, the patients dying not so much from the effects of the inflammation as the rapid introduction into the general circulation from the peritoneal cavity of preformed septic material. In suppurative peritonitis the primary microbic cause is less in quantity or virulence and a sufficient length of time intervenes between the beginning of the attack and the operation or death for the formation of pus and other inflammatory products. Every acute peritonitis is septic in so far that phlogistic substances reach the general circulation from the inflammatory lesion, and in that frequently the inflammation terminates in suppuration, but the term septic should be limited to those cases of diffuse septic peritonitis in which, as a rule, death occurs in a few days and before any gross pathologic conditions have had time to develop. It is a disease that is almost uniformly fatal, with or without operation, the patients dying from the effects of progressive sepsis. The claim of operators to have cured such cases by laparotomy must be accepted with a good deal of allowance. The microbes which produce this form of peritonitis are those which follow the lymphatic channels and are rapidly diffused not only over the entire peritoneal surface, parietal and visceral, but also through the subserous lymph spaces. Acute general septic peritonitis is essentially a streptococcus disease. The disease is observed most frequently after perforation into the free peritoneal cavity in the region of the small intestines of an abscess containing septic pus, rupture or perforation of any of the abdominal or pelvic viscera containing septic material, gunshot or stab wounds of the abdomen with visceral injury of the gastro-intestinal canal, and occasionally as the result of infection during a laparotomy. The gravest form of puerperal sepsis is a diffuse septic peritonitis. The subjects of this variety of peritonitis die so soon after the beginning of the disease, that at the postmortem, or if the abdomen is opened during life, at the operation, no gross tissue changes are discovered. Beside a slightly increased vascularity, nothing is found to indicate the existence of peritonitis. The septic material formed in large quantities and of intense virulence is rapidly absorbed by the stomata of the under surface of the diaphragm, discovered and described by von Recklinghausen. In putrid peritonitis the streptococcus infection is complicated by the presence of putrescible substances, which serve as a nutrient medium for saprophytic bacteria which modify the character of the inflammatory product. It occurs most frequently in connection with grave forms of puerperal nephritis. It is usually associated with more or less gangrene or ulceration of the organ or parts primarily affected, as uterus, intestine or abdominal wall. It is diffuse septic peritonitis that has so far proved so obstinate to successful surgical treatment. Surgery has done much toward its prevention, but very little toward saving life after the disease is once fully developed. Careful analysis of the cases which yielded to laparotomy would undoubtedly disclose the fact that most of them were not genuine cases of general septic peritonitis, but cases of more or less localized inflammation of the peritoneum with or without suppuration. In this opinion I am supported by no less an authority than Frederick Treves (*The Practitioner*, London, June, 1894), who, from a surgical standpoint, divides peritonitis into localized and diffuse. He states that the surgical treatment of the former has yielded encouraging results, but in general non-tubercular peritonitis it has been phenomenally unsuccessful. After speaking of circumscribed peritonitis the same author ("The Surgery of the Peritoneum," *British Medical Journal*, Oct. 3, 1896) says: "Peritonitis in the 'small intestine area' is, on the other hand, rapidly diffused and is as rapidly attended by septicemic symptoms. In the treatment of localized peritonitis surgery can claim to have made great advances, but in the treatment of diffuse peritoneal inflammation with marked constitutional symptoms there is little progress to record. The abdomen may be opened, washed out and drained, and the distended bowel may be relieved of its putrescent contents by incision, but the results at the best are not brilliant, and it is evident that the treatment of this terrible complication must still incline toward that desirable prevention which is better than cure."

I have opened, drained and washed out the peritoneal cavity in many cases of diffuse septic peritonitis and, I am free to confess, without a single successful result. All of my cases died a few hours to a day or two, after the operation, of sepsis in spite of heroic stimulation and, in some cases, of frequently repeated irrigation with sterilized water, normal solution of salt, or mild antiseptic solutions such as boracic acid and acetate of aluminium. On the other hand, some surgeons report a fair percentage of recoveries after laparotomies for what they call general septic peritonitis. Krecke (*Münch. med. Woch.*, No. 33, 34, 1892) has collected 119 cases of laparotomy in general peritonitis, the origin of which was determined in all except 18, of which 9 died and 9 recovered. In most of the cases the disease was caused by perforation. Of these 36 followed perforation of the appendix, 12 were cases of typhoid perforation, of which 5 recovered; 12 were due to perforation from gangrene and other causes implicating the intestines. Of the gangrenous variety not one recovered, and of the 8 others only 3 were cured by the operation. Of traumatic cases, 3 of punctured and 1 of gunshot wound all recovered, but of contusions only 3 out of 8 recovered. The operation saved 5 out of 13 cases of puerperal peritonitis. Lastly a group of cases of peritonitis from various other causes yielded 3 deaths and 6 recoveries. The total result is 119 cases of general peritonitis treated by laparotomy, 51 recoveries and 68 deaths.

A. J. McCosh (" The Treatment of General Septic Peritonitis," *Annals of Surgery*, June, 1897) operated (1888 to 1895 inclusive) in forty-three cases of general septic peritonitis. Of these thirty-seven died and six recovered, a mortality of about 86 per cent. A free abdominal incision was made in all, and with few exceptions irrigation was employed.

It is not easy, nor always possible, to ascertain the extent of inflammation *in vivo* by opening the peritoneal cavity, and a strong suspicion remains that at least in some of the cases which recovered the peritonitis was not general, or that the operation was performed before the entire serous surfaces were involved. Certain principles in the medical and surgical treatment of peritonitis are applicable to all forms of the disease and the best place to discuss them is in connection with the gravest variety—acute general septic peritonitis.

Medical treatment.—A more general discussion of the medical treatment of peritonitis is out of place here, but a few words in reference to what the surgeon should do and what he should not do in the way of medical treatment when he assumes charge of a case of peritonitis is pertinent to my subject. Stomach feeding must be limited to the administration of liquid food and stimulants. If, as is so frequently the case, nausea and vomiting are prominent symptoms, rectal enemata are of the greatest value. The distressing thirst can often be effectually relieved by high rectal enemata of warm water; if these are not tolerated, by hypodermatic infusion. The therapeutic indications for cathartics and opium in the treatment of peritonitis are not definitely settled. Some favor cathartics, others condemn them and rely on opium. Mr. Tait has taught us years ago the value of saline cathartics in the prevention of peritonitis and in its treatment during the incipient stage. Most practitioners have adopted his views and administer saline cathartics as soon as the first symptoms make their appearance, and certainly the results have been much better since this practice has come into more general use. It is not only clinical observation that supports Tait's teachings and practice, but his views have been substantiated by experimental investigations. The experiments of Wegner prove that bacteria injected into the peritoneal cavity readily enter the blood vessels and lymphatics and thus reach the excretory organs, notably the intestinal canal, through which they are rapidly eliminated by free catharsis.

Lawson Tait (" Diseases of the Ovaries," fourth edition) has found the most efficient treatment for septic conditions following abdominal section to be 30 or 40 grains of sulphate of magnesia, repeated every hour or every other hour until the bowels move freely. Hence, where microbes accumulate in such quantities that nature unaided can not remove them, it is rational treatment to render assistance by the administration of saline cathartics to favor the process of elimination.

I have seen many cases of threatened peritonitis after abdominal section aborted by the timely administration of saline cathartics. If the stomach is intolerant, calomel in small doses, repeated hourly, and saline enemata are indicated.

One of the great dangers in peritonitis is rapid distension and paresis of the intestines, conditions which are provoked by opium and which can be most effectually averted by early and free catharsis. The use of cathartics is absolutely contraindicated in all cases of peritonitis caused by perforation. In such cases the use of opium is legitimate and useful as it diminishes shock, extravasation of septic material and its rapid diffusion over the peritoneal surface. Peritonitis, especially the septic variety, invariably depresses the heart's action, a condition which should be met by active stimulation. Shock, general debility and, as Fritsch has shown, a weak heart increase the danger from sepsis. Strychnia, camphor and alcoholic stimulants should be employed early and at short intervals in all cases of grave peritonitis. If these remedies are not retained by the stomach they must be administered subcutaneously or per rectum. The application of ice or the cold coil over the abdomen frequently succeeds in diminishing the tympanites and should be employed to prevent over-distension and paresis of the intestines when this condition appears and the peripheral circulation warrants their use. If the heart's action is weak and the capillary circulation sluggish, hot applications are more agreeable to the patient, and a better stimulant for the feeble peripheral circulation.

Operative treatment.—There can be no difference of opinion in reference to the advisability of early operative treatment in the management of general diffuse septic peritonitis. Without operation death is certain. An early operation may succeed in arresting further extension of infection in cases in which the disease would become diffuse, and in diffuse cases may occasionally be the means of saving a life which without it would be surely lost. An early diagnosis and prompt operative interference are the conditions *sine qua non* for success. The patient should be properly prepared for the operation, not only with a view of securing absolute asepsis for the field of operration and everything that is to be brought in contact with wound, but the necessary precautions should also be carried into effect to sustain the heart's action and stimulate the capillary circulation during and immediately after the operation. This can be accomplished by administering a 1-32 grain of strychnia, if the patient is an adult, hypodermatically and two ounces of whisky or brandy by the stomach or rectum half an hour before the anesthetic is administered. I am partial to the use of sulphuric ether as an anesthetic in performing laparotomy for this indication, as it has a less injurious effect on the already enfeebled circulation than chloroform. The body must be carefully protected against loss of heat during the administration of the anesthetic and the operation by warm flannel blankets and bottles or rubber bags containing hot water.

The normal salt solution, sterile water or antiseptic solutions which are to be used for irrigation must be kept at a temperature of 110 to 120 degrees F.

Different kinds of drains and drainage material should be on hand to be used as indications may arise.

The handling of the patient must be done with the utmost care and gentleness.

History of operation for peritonitis.—Abscesses which had their origin in the peritoneal cavity have been opened for centuries, after they presented themselves as such upon any of the accessible surfaces. Laparotomy as a therapeutic resource in the treatment of peritonitis is of recent date. J. Ewing Mears, as early as 1875, operated by abdominal section in a case of circumscribed suppurative peritonitis following childbirth. He advocated at that time surgical intervention in all cases of suppurative peritonitis. Treves ("The Treatment of Acute Peritonitis by Abdominal Section," *Brit. Med. Journ.*, March 14, 1885) reported a case of acute peritonitis treated by abdominal section in 1885, which terminated in recovery, and he recommended the operation in similar cases. During the same year Péan (*Gaz. des Hôp.*, Nos. 49, 51 and 60, 1885) advocated in the treatment of septic peritonitis incision, toilette and drainage of the abdominal cavity. He favored a large median incision, removal of inflammatory product with sponges and napkins, closure of wound by suturing, except a place large enough for drainage. About the same time Oberst ("Ein Fall von Perforations Peritonitis, Laparotomie, Tod nach 9 Wochen," *Centralblatt f. Chirurgie*, No. 20, 1885) urged energetic surgical treatment in cases of acute peritonitis. In the acutest form, however, he admitted that abdominal section and drainage were powerless in averting death from sepsis. In 1886 Lawson Tait ("Discussion on Abdominal Section," introduced by Mr. Lawson Tait, *Edinburgh Medical Journal*, May, 1886) reported two cases of acute peritonitis treated by abdominal section, of which one recovered. He advised laparotomy in all cases of peritonitis if an effusion can be demonstrated and the existence of fever indicates the pyogenic nature of the inflammatory product.

In 1889 ("Traitement Chirurgicale de la Péritonite," *Presse Méd. Belge*, No. 49, 1889), successful laparotomies for septic peritonitis were reported by Demons, Bouilly, Dernuce, Brun, Labbé and Routier. It is evident that in most of these cases the operation was performed for circumscribed suppurative and not for diffuse septic peritonitis.

The treatment of peritonitis by laparotomy received a new impulse when, about nine years ago, it was found that the disease is so often produced by primary suppurative and perforative lesions of the appendix vermiformis. About the same time gynecologists began to treat suppurative lesions of the pelvis, so frequently the precursors of a similar affection of the peritoneum, upon sound surgical principles. The old dictum, *ubi pus ibi evacuo*, is now fully appreciated by surgeons and gynecologists, and is daily put in practice in the treatment of suppurative ectoperitonitis and septic and suppurative peritonitis. Future clinical experience and experimental research will make this department of surgery one of the greatest blessings to humanity.

Incision.—In the operative treatment of general septic peritonitis authorities are as yet not agreed as to the size, location and number of incisions that should be employed in opening the abdominal cavity. In circumscribed peritonitis, the rule to open and drain by the shortest and most direct route is usually followed. In perforation of any other organ except the appendix vermiformis, resulting in diffuse peritonitis, the first incision should always be made at or near the median line. The incision is made above the umbilicus if the gall bladder, stomach or duodenum is the seat of perforation, below the umbilicus in perforation of any other portion of the small intestines.

Mikulicz ("Weitere Erfahrungen über die operative Behandlung der Perforations Peritonitis," *Archiv f. klin. Chir.*, B. 39, p. 756) makes a sharp distinction in the treatment of diffuse septic and progressive fibropurulent peritonitis. In the former variety the abdominal incision should be large, the perforation closed and the abdominal cavity disinfected and drained. In the latter the adhesions should be carefully preserved and the different pus accumulations opened and evacuated separately. Some surgeons prefer to open the abdomen some distance from the linea alba.

Ramsay (London *Lancet*, Nov. 30, 1895) gives cogent reasons why in opening the abdominal cavity the incision should not be made in the median line, but through the center of either rectus muscle where the abdominal wall is thickest and strongest, and where the different layers can be sutured separately with the greatest ease, and where for these reasons ventral hernia is least likely to follow as one of the remote consequences of the operation. Prolonged drainage is always an important etiologic element in the occurrence of post-operative ventral hernia, and this complication is certainly less likely to follow if the incision is made through the muscular portion of the abdominal wall than through the thin fibrous linea alba.

In the treatment of diffuse septic peritonitis the incision should be at least large enough to insert the hand for the purpose of making a careful intra-abdominal exploration with a view of ascertaining the extent of the disease and to locate and, if possible, treat the primary lesion. Gill Wylie (*Medical Record*, Feb. 15, 1890) recommends in the surgical treatment of diffuse peritonitis an incision of this size to enable surgeons to break up all adhesions among the intestines, and to freely wash the entire cavity of the peritoneum and insert two or more drainage tubes. The question relating to the propriety of breaking up adhesions will be discussed elsewhere, as in the form of peritonitis that is under consideration now adhesions, as a rule, are absent or, if present, few and slight. As I have stated before, the incision should be large enough to enable the surgeon to find and treat the primary affection which caused the peritonitis.

Mr. Bowlby (*Brit. Med. Journ.*, Oct. 27, 1894) is of the belief that an incision below the umbilicus does not necessarily empty the peritoneal cavity. In one case, after incising and flushing out through a subumbilical incision, he found a large quantity of gas as well as fluid remaining in the peritoneal cavity above. In cases of peritonitis resulting from perforation of a gastric or duodenal ulcer he advises two incisions (one above and one below the umbilicus), to ensure complete flushing. In diffuse peritonitis incisions should be made at a number of points with a view of facilitating irrigation and of ensuring free drainage. The best points will be above the pubes and above the umbilicus, and posteriorly through the lumbar region on each side; in the female through drainage into the vagina, by incising the Douglas *cul-de-sac*, will answer an excellent purpose. A long incision, permitting the intestines to escape from the abdominal cavity and covering them with a piece of gutta-percha or rubber tissue which is sutured to the margins of the wound, a method of treatment suggested by Hadra of Texas, is based entirely upon theoretic grounds and is too hazardous to merit a trial.

McBurney has devised an incision for operations on the appendix that reduces to a minimum the risks of a subsequent formation of a ventral hernia (*Annals of Surgery*, July, 1894). "The skin incision is oblique, about four inches in length, crossing at a right angle a line drawn from the spine of the ilium to the umbilicus, and about an inch from the spine. This incision is a little to the outer side of the normal situation of the appendix. The fibers of the external oblique and its aponeurosis are not cut, but are separated with great care in the direction in which they run. When the edges of the wound of the external oblique are separated with retractors a considerable expanse of internal oblique muscle is seen, the fibers of which cross somewhat obliquely the opening formed by the retractors. With a blunt instrument the fibers of the internal oblique and transversalis muscles can be separated without cutting more than an occasional fiber in a line parallel with their course, that is, nearly at right angles to the incision in the external aponeurosis. Blunt retractors are now introduced, and these expose the transversalis fascia, which is then divided in the same line; last of all, the peritoneum is divided." This incision is an ideal one in the removal of a diseased appendix not complicated by suppurative periappendicitis. In the latter event the incision must be large enough to enable the surgeon to see what he is doing in order to avoid injuring important neighboring organs. It will be seen from what has been said that no fixed rules can be laid down and followed in regard to the size, location and number of incisions to be made in opening the abdominal cavity for peritonitis. The surgeon must be guided by his own judgment and adopt plans and methods applicable to each individual case rather than follow, as is only too frequently done, a routine practice.

Eventration.—A number of surgeons favor eventration after incising the peritoneal cavity freely for the purpose of effecting more thorough disinfection. In septic peritonitis the serous coat of the intestines is always damaged and frequently the muscular coat in a condition of paresis. The intestines are also usually very much distended. These conditions render them very liable to be injured and even ruptured when extensive eventration is made, to say nothing of the shock which always attends such a procedure, notwithstanding that the greatest care is exercised in protecting them with warm moist compresses.

Olshausen ("Todesursache nach Laparotomie," *Virchow's Jahresbericht*, 1887) has called attention to the danger of eventration and prolonged exposure of the healthy intestines in abdominal operations. He reported several cases in which adynamic ileus and death followed laparotomy which could be traced to no other cause. Gusserow recognizes the danger from these sources and guards against them by retaining the intestines in the abdominal cavity with large flat sponges. If such baneful results follow eventration and exposure of healthy intestines it is not difficult to conceive that the danger from the same source in laparotomy for peritonitis would be increased tenfold. The feeble circulation, the increased sensitiveness of the inflamed viscera in such cases would necessarily greatly increase the shock and aggravate the already existing intestinal paresis. If eventration is practiced for the purpose of relieving the over-distended intestines a limited part of the intestine should be brought forward into the wound. When prolapsed the loop is incised or punctured, emptied of its contents, the visceral wound sutured and the loop douched with hot water, dried and returned. Extensive eventration is dangerous and must be scrupulously avoided. I have many a time seen the dangers of extensive eventration in the operative treatment of intestinal obstruction, and wherever possible I am only too anxious to reach the object for which the operation is performed without it.

Irrigation.—The subject of irrigation in the surgical treatment of peritonitis has been frequently discussed, but so far no positive final conclusions have been reached. Some surgeons invariably irrigate, others believe that irrigation does more harm than good and are content to remove the inflammatory product by means of sponges. It is generally conceded that in diffuse peritonitis it is impossible, by any known methods of irrigation, to remove all of the infectious material from the peritoneal cavity. In diffuse septic peritonitis the patients die from the effects of sepsis caused by the absorption of septic material from the peritoneal cavity, and the surgeon resorts to irrigation almost instinctively to diminish the danger from this source. The use of strong antiseptic solutions has been abolished owing to the danger from intoxication resulting from the rapid absorption of the antiseptic employed and the damage which results from the irritating germicides when applied to the endothelial cells lining the viscera and the peritoneal sac. Sterilized water, normal physiologic solution of salt, solutions of boracic acid and acetate of aluminium and Thiersch's solutions are now most frequently used in washing out the peritoneal cavity. Whatever medium is employed should be used at a temperature of 110 to 115 F., and the stream should be sufficiently large and strong to wash out the most remote corners of the peritoneal cavity in the direction of the drainage opening or openings.

Reichel's ("Deutsche Zeitschrift f. Chirurgie," B. xxx) experimental attempts to successfully treat septic peritonitis, artificially produced in animals, were almost entirely a failure. Irrigation of the peritoneal cavity with sublimate, chloroborate of soda, salicylic acid, etc., were useless; the animals quickly perished. Laparotomy performed after the introduction of fecal matter, for the purpose of cleansing the peritoneal cavity, and prior to the development of peritonitis, according to Reichel, is not only useless, but even in healthy animals, proved to be an injurious measure. Somewhat better results were obtained by gently sponging the peritoneal surfaces, after opening the abdominal cavity, with gauze sponges, and employing the Mikulicz gauze drain. In nine experimental cases in dogs, two recoveries were obtained by this method. Reichel believes successful operative treatment is applicable only in cases of circumscribed empyema-like pus accumulations.

Delbet ("Recherches expérimentales sur le Lavage du Péritoine," *Ann. de Gynæcologie*, September, 1889) speaks more favorably of the results of irrigation of the peritoneal cavity in cases of general peritonitis from an experimental standpoint. He ascertained by experiments on animals that if the peritoneal cavity is irrigated for ten minutes with a physiologic solution of salt, toxic substances can be introduced without causing peritonitis or death from intoxication if the infection is followed by another irrigation with the same solution. He advocates the use of salt solution in operations on the abdominal cavity when contamination takes place during the operation and in the operative treatment of septic peritonitis.

Mr. Barker (*British Med. Jour.*, 1894, p. 920) has found by experience that a very convenient method of flushing the abdominal cavity is to use a can with three taps to which tubes of large caliber are attached, and thus the peritoneal cavity can be flushed from several points at once, the fluid flowing out through the original incisions. He uses fluids for flushing at 105 degrees F.

Wiggin (*Medical Record*, Aug. 11, 1894) believes that the use of peroxid of hydrogen, followed by plenty of normal salt solution, is most beneficial in disinfecting peritoneal cavity, and in preventing adhesions. He claims that many otherwise successful laparotomies are followed by such extensive and painful adhesions that the patients are left in a worse state than before operation, and the observance of this simple rule would avoid such a disagreeable result. Continuous irrigation so useful in the treatment of septic wounds in other localities has been suggested in the treatment of general peritonitis. In 1894, Oscar Allis (*Annals of Surgery*, 1894, p. 179) recommended in the treatment of general septic peritonitis abdominal section, liberation of pus from all pockets by tearing adhesions, continuous irrigation, the local application of cerate to the walls of the suppurating cavities, the prone position and to keep the wound open by tucking a rubber dam covered with cerate between the abdominal wall and the intestines on each side, with one border emerging from the incision. He believes that under a continuous system of flushing or irrigation the wash products would be made to float constantly to the surface, and be more effectually carried off than by dependent dorsal drainage. The peritoneal cavity can not be flushed continuously for any length of time, as adhesions will soon form around the drainage tubes and between the intestinal coils. In acute septic peritonitis, however, continuous drainage deserves a fair trial. The fluid to be used should be introduced into the lowest portion of the abdominal cavity through a non-fenestrated rubber tube and seek escape through the rubber tubes above the umbilicus and in the lumbar regions.

The propriety of tearing up adhesions for the purpose of making the irrigation more thorough is very questionable and as a rule should be avoided. The so-called toilette by using sponges must be done with the utmost gentleness, if resorted to at all, as all mechanical insults inflicted on the endothelial surface are sure to aggravate the existing conditions. If it is intended to remove the fluid from the peritoneal cavity it is better to do so by placing the patient on the side so as to pour it out instead of removing it by mopping. If no irrigation is employed and the peritoneal cavity contains a transudate of serum or pus the fluid should be disposed of in the same way when the more thorough cleansing can be effected by the gentle use of a soft sea-sponge.

Incision of overdistended intestine.—One of the most unfavorable conditions in peritonitis is overdistention of the intestines with gas and septic fluid material. A paretic inflamed intestine is permeable to pathogenic microbes, thus adding another fruitful source of infection to the existing septic inflammation. Death in peritonitis is the result more of rapid intoxication than the inflammation itself. The inflammation of the visceral peritoneum of the intestines leads to paralysis of the muscular coat, rapid distension and the escape of preformed toxins and bacteria. Boennecken's experiments have shown that the latter takes place in a remarkably short time. It is natural that surgeons should have made attempts to remove the distension and unload the intestines of septic material by tapping or by making one or more visceral incisions.

Mixter (*Boston Medical and Surgical Journal*, 1895, No. 9) advises this procedure in grave cases of general peritonitis. He recommends incision of the coils of the paretic intestines at as many points as may be necessary to thoroughly evacuate them. The intestine should be drawn out of the wound, held over a basin, incised in from one to four places and thoroughly emptied, after which the coils should be quickly washed off with a hot saline solution, the visceral wounds sutured, the intestine returned and the abdominal incision closed. Mixter has resorted to this procedure in nearly twenty cases, some of which recovered, and in those that died the visceral wounds were found to be tight. In some cases, particularly in those that have had an abdominal incision on the right side, the author secures permanent drainage by introducing a tube into the most prominent part of the cecum and retains it as long as necessary. Through this tube medicines and nourishment may be introduced if the stomach is not retentive. In a paper read before the Royal Medical and Surgical Society, Mr. C. B. Lockwood advocated puncture and incision of the paretic intestine in cases of diffuse septic peritonitis treated by abdominal section. Incision of the intestine for the purpose of relieving distension and evacuating septic contents was favored by Hulke, Knowsly Thornton and Barker. In the few cases in which McCosh incised the intestine he noted that it did not relieve the distension for a distance of more than ten or twelve inches. The writer has made visceral incisions in a number of cases in which the intestine had become paretic and although but one of the cases recovered he is fairly convinced that it is almost essential to success in such desperate cases. I am in the habit of placing the patient on the side and bringing the most distended part of the intestine well forward into the wound and making a transverse incision about an inch in length opposite the mesenteric attachment. As the intestinal wall does not contract evacuation should be secured by pouring out the contents from above and below the incision by grasping the intestine some distance from the incision and bringing it above the level of the visceral incision. By this method several feet of intestine can be evacuated through one incision. After thorough cleansing of the exposed intestinal surface with warm salt solution, the wound is sutured in the usual manner and the intestine returned. If more than one incision is made I can readily conceive that irrigation of the intestinal tract between them with a warm normal solution of salt would secure a more thorough cleansing of that part of the intestinal tract and would be a potent means of restoring intestinal peristalsis.

Drainage.—Drainage of the abdominal cavity after operations for peritonitis is an admission of the present imperfect state of surgery. It is an acknowledgment on the part of the surgeon that he has only in part fulfilled the indications for which the operation was performed; it is a confession that he was not able to accomplish what was so much needed and what he so earnestly desired—complete asepsis of the entire peritoneal cavity. With the means at our disposal at the present time drainage in the surgical treatment of peritonitis is an unavoidable evil. The question that confronts us now is not when but how to drain in such cases. In 1870, during the Franco-Prussian War, Marion Sims made a special study of the cause of death in cases of gunshot wounds of the abdomen. The result of his observations led him to the conclusion that, independently of shock and hemorrhage, death resulted from sepsis. He found that with few exceptions, if the bullet entered above the pelvis the case was fatal, while similar wounds of the pelvic portion of the abdominal cavity ended in recovery. He ascribed this difference in the mortality to the circumstance that high wounds resulted in extravasation of intestinal contents which accumulated in the pelvic cavity, while in pelvic wounds the track made by the bullet served as a drainage canal. In 1872 he recommended that in all penetrating wounds of the abdomen and in operations on any of its contents, drainage should be established. In ovariotomy he recommended tubular drainage through the wound and vagina, using for this purpose a large rubber drain. Very few surgeons at the present day would feel justified in opening the abdominal cavity for peritonitis and dispense with drainage. Voices have, however, been raised against too frequent resort to drainage, among them Olshausen ("Ueber Marion Sims," 1896), who says: "Drainage of the peritoneal cavity is an illusion. Drainage to be of service must be limited to the evacuation of preformed pathologic spaces."

Removal of fluid pathologic products by gentle sponging accomplishes the same object. The absorptive power of the peritoneum should be preserved as much as possible by handling with the utmost gentleness. Prolonged and rough manipulation of the intestines is productive of great shock. Drainage is always attended by the danger of putrefaction bacilli entering into the peritoneal cavity. In perforating wounds he recommends a careful cleansing, complete hemostasis, avoiding drainage in all recent cases.

Barker ("Remarks on the Limits of Drainage in Suppurative Conditions of the Abdominal Cavity," *British Med. Journal*, May 25, 1896) has largely dispensed with drainage of the abdominal cavity for suppurative lesions. He relies mainly on thorough flushing and sutures the abdominal incision. He only resorts to drainage in the treatment of putrid abscesses caused by appendicitis. If a drain is used in exceptional cases of peritonitis he advises its removal at the expiration of twenty-four hours. The difficulties encountered in draining the peritoneal cavity become very apparent in following the work of Bardenheuer ("Die Drainirung der Peritoneal Höhle," 1881). He describes four methods in operations on the abdominal and pelvic cavities of women. The first method is by a T-shaped tubular drain of which only the transverse piece is fenestrated and the vertical portion brought out behind the uterus into the vagina. The second method consisted in using two instead of one transverse drain, fastened together, of which the four ends were sutured to the pelvic floor with catgut. The third method had in view the prevention of prolapse of the intestines by using a fenestrated rubber plate above the drains, which was sutured to the pelvic peritoneum. This method proved useful for the first four to six days; after this time putrefaction of the contents of the cavity invariably set in. The subsequent removal of the plate through the vagina also proved troublesome and often deleterious. The last method consisted in the use of a catgut net with meshes 6 centimeters wide, sewed to the pelvic floor above the two rubber drains. The pelvic peritoneum was always united to the vaginal mucous membrane with suture. This method proved eminently satisfactory, but I doubt if it still remains in use in his practice; certainly it has never been generally adopted.

(*To be continued.*)

ORIGINAL ARTICLES.

CELANDIN, ITS PHARMACOLOGY, PHYSIOLOGIC ACTION AND THERAPY.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY JOHN V. SHOEMAKER, M.D., LL.D.
PHILADELPHIA, PA.

Celandin is the whole herb of the *chelidonium majus* of the natural order *papaveraceæ* and grows both in Europe and North America. The plant contains two alkaloids, chelidonin and sanguinarin. These exist in combination with chelidonic acid. A bitter, yellow, crystallin substance, termed chelidoxanthin by Probst is also a constituent, besides tannic acid, starch, cellulose, etc.

Celandin has an acid, bitter taste. Taken internally in small doses it has an appetizing and tonic effect and stimulates the intestinal glands, liver, kidneys and bronchial mucous membrane. In large quantities it causes vomiting and purging. The fresh milky juice of the plant has a local irritant action. By virtue of this property it has long been popularly used as an application to warts and corns. Internally celandin was anciently given for the relief of catarrhal jaundice.

From its power in the removal of papillary outgrowths Dr. Denissenko, a Russian physician, conceived that the fresh juice of chelidonium majus might prove beneficial in epithelioma. This observer made trial of the remedy in a number of cases and published some highly favorable results. He employed the drug both internally and externally, giving from twenty-four to seventy-five grains daily of the extract in watery solution. At the same time he made injections at several points into the tumor near to its border of a mixture of equal parts of extract of chelidonium, distilled water and glycerin. In cases of ulceration he painted the surface with the same glycerin extract. He states that after several days of this treatment there form at the points of injection, fistulous tracts, around which the tumor disappeared. In fifteen to twenty days later, according to Denissenko, the diseased is clearly separated from the healthy tissue and the tumor is diminished by half: in some cases it is entirely gone and the enlargements of the glands have subsided. In support of his statements the author reported a series of cases in which cure or marked amelioration occurred. His results have been subsequently both confirmed and denied by different writers.

Any remedy which is claimed to exert a favorable influence on so grave a malady as carcinoma deserves the most careful and impartial study. Accordingly, in order to repeat these experiments I procured a sample of *chelidonium majus* and had prepared from it the mixture of extract, distilled water and glycerin recommended. A number of cases of epithelioma were subjected to Denissenko's method, which was faithfully carried out in every particular. A brief account of a few of these may here be given.

A lady 63 years of age had noticed a dry, papillary growth upon the lower lip for about two months. The tumor was small in size, dry, wart-like in appearance and the seat of occasional stinging pain. There was no ulceration. At times the patient picked at the little tumor and caused the exit of a few drops of blood. Otherwise there was no discharge. The neighboring glands were not involved.

A second lady of about the same age, had been afflicted with a hard, dry, wart-like excrescence upon the left cheek a short distance external to the chin for about three months. The lesion was moderately painful and had very slowly enlarged. It was about half an inch in average diameter, its outline being rather oval. Here also was no implication of the glands.

Both the preceding cases, therefore, being typical superficial epithelioma not far advanced, attended by no glandular or systemic complication—in other words as yet local lesions—might fairly be regarded as particularly amenable to any treatment having power to influence carcinoma.

A third case exhibited epithelioma of the lip in a more advanced stage. The sufferer was a man aged 70 years, in whom the disease had existed for seven months. It had gone on to ulceration and there was the characteristic sore with its steep, hard edges, indurated base and raw, red surface with a tendency to hemorrhage. There was slight enlargement of submaxillary glands but no cachexia. This case was less favorable to any treatment but nevertheless was by no means hopeless.

In a fourth case the patient was a man in whom epithelioma had existed for ten months. He gave his age as 46 years, which is rather early for the advent of this disease. The lesion made its appearance as a dry scab on the tip of the nose. The patient scratched the scab off but it soon redeveloped and from that time the affection had continuously and progressively spread. In the beginning the sore had been dry, but at a later period it discharged a thin seropurulent matter when picked. He had not experienced much pain but at times a tingling or stabbing sensation affected the nose. Latterly he had begun to suffer from pain radiating from the nose into the temple and forehead. The surface had ulcerated.

A woman 66 years of age, was afflicted with an epithelioma of the right cheek. The disease had begun a year previously as a hard crust which gave no pain. In the course of a few weeks the crust had fallen, leaving a dry, scaly base. There was no redness of the surrounding skin. The spot of disease began to enlarge and the surrounding skin became red. The lesion was very hard to the touch. For two months the surface had been ulcerated and was the seat of extreme lancinating pain.

I made use of celandin in other cases of epithelioma in different stages and different situations, but it is unnecessary to cite the histories of case after case. I followed precisely the directions given above as to injections, painting the surface and internal use of the drug. I regret very much to be obliged to say that I could observe no appreciable effect on the growths. The remedy seemed to exert in some cases a certain tonic influence but beyond that action was of no value. I am consequently unable to corroborate the results of Dr. Denissenko.

An experience similar to my own has been reported by a number of Russian physicians. In some cases these observers saw collapse follow administration of the remedy. Kalabine made the same observation as myself, viz., some amelioration of the general condition and increase of strength but no local effect. Botkine has recorded an unsatisfactory experience. Nevertheless, it is proper that clinical investigation should be continued Dr. Samson journeyed from England for the express purpose of visiting Dr. Denissenko, studying his methods and observing his results and was led to the belief, from what he saw, that the treatment has a basis of merit. Dr. Robinson of Constantinople, has published the history of a case in which the use of celandin was followed by marked improvement.

There is no doubt that the local application of the juice of *chelidonium majus* will destroy certain non-malignant hypertrophic lesions as warts, corns and callosities. It may also be serviceable in chronic eczema; in fact in all hypertrophic conditions of the integument due to perverted nutrition or chronic inflammation. I am of the opinion, however, that it will be found destitute of influence upon the development of heterologous, malignant neoplasms.

CARVACROL IODID.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa, June 1-4, 1897.

BY ARTHUR H. COHN, PH.G., M.D.
MILWAUKEE, WIS.

This substitute for iodoform is offered to the profession because of the unpleasant odor, often irritating character and, last but not least, of the non-antiseptic properties of the latter. It is a well known fact that iodoform is not an antiseptic, so we must look forward to a preparation which will fulfil our wants. Bacteriologists have proven that cultures of pathologic and non-pathologic bacteria may be propagated on it. Shirmunski demonstrated the non-antiseptic properties of iodoform as follows: He added to a gelatin solution iodoform and sterilized water; this mixture again was poured into shallow dishes, allowed to evaporate, on which iodin was liberated, but nevertheless bacteria grew on this culture medium. He also experimented by mixing staphylococci and streptococci with iodoform, but after making culture from the mixture found that not only were the pus germs propagating, but also that bacteria which were originally found in the iodoform were multiplying. Only freshly prepared iodoform was found to be free from bacteria in some cases.

Dry heat or steam, or washing with ether, can not be applied in sterilization of iodoform, on account of the two former decomposing it and the latter leaving scales upon evaporation. Corrosive sublimate can not be used because the red iodid of mercury results. Washing with solution of carbolic acid was also recommended, but was found to be uncertain. It will easily be seen how difficult it is to obtain a sterile preparation of iodoform, and it is no wonder we are looking forward to a preparation which will take its place.

The preparation which I should recommend to the profession for consideration is iodocrol or carvacrol iodid. Carvacrol is an isomer of thymol, differing only in relative position of the hydroxyl groups in the nucleus. It is manufactured in the following manner: Two grams of carvacrol and thirty-eight grams of potassium iodid are dissolved in 40 c.c. of a 10 per cent. aqueous solution of sodium hydrate. To this a solution of chlorinated soda is gradually added under continuous stirring until no more of a precipitate is found. During the reaction the mixture is kept cool by placing the vessel in cold water. The precipitate is collected on a filter and first washed with water to which a very small quantity of alkali has been added, and then with pure water. It is then allowed to dry at the temperature of the room. The product is a bulky, grayish yellow or buff-colored amorphous powder having a faint aromatic odor. It is soluble in ether, chloroform, benzin, carbon disulphid, volatile and fixed oils. From its solution in ether and chloroform it is precipitated on the addition of alcohol, becoming paler in color. This purified product did not show signs of shrinkage until above 170 degrees C., and at 200 degrees C. had become tarry and black, but not liquefied. It combines the antiseptic properties of carvacrol with those of iodin and possesses the advantage over iodoform in being odorless or nearly so, and in being five times as bulky.

Experiments have been made to grow staphylococci and streptococci on carvacrol iodid, but with negative results, thus proving it to be a true antiseptic. It may be used as a dusting powder, either pure or diluted with boracic acid. In the treatment of the nose and throat it is best used in a solution of almond oil or olive oil. It has been used as a dressing for wounds to a great extent in Milwaukee in the National Home of Volunteer Soldiers. It is also manufactured into gauze. It may be used with great benefit in almost all surgical dressings; eczema, pruritus, chancres, chancroids, etc.

In conclusion, I would say that this preparation has so many advantages over iodoform, especially so of being a true antiseptic, that I sincerely recommend it to the profession and hope it will be given a fair trial.

A NOTE ON TWO NEW CREOSOTE COMPOUNDS: CREOSOTE VALERIANATE AND GUAIACOL VALERIANATE.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association at Philadelphia, Pa., June 1-4, 1897.

BY FRANK WOODBURY, M.D.

PHILADELPHIA, PA.

In these days of new remedies of ephemeral usefulness and evanescent reputation, it is refreshing to take up, for brief consideration, a drug with an established record of more than half a century. We recall the fact that while experimenting with tar from beech-wood, Reichenbach, in 1832, first obtained a fluid substance, which, on account of its possessing pre-eminently the power of preventing putrefaction in organic substances, he termed "creosote," or "flesh preserver." That expert chemist also fully recognized the fact that the new chemic agent was not a simple, but a very complex, substance, being composed principally of hydrocarbons of the aromatic group. It also contains a variable quantity of water. According to a recent authority, Marasse, it contains phenol, cresol, phlorol, guaiacol and creosol; also methylcreosol and the methylic ethers of guaiacol, phlorol, etc. By fractional distillation, Hofmann separated the dimethylic ethers of pyrogallol, of methyl-pyrogallol and of propyl-pyrogallol from that portion of the creosote which passes over at a temperature above 220 degrees. Hofmann discovered a new body, which he named coerulignol, possessing powerful toxic properties and which should be carefully removed from creosote that is designed to be used for medicinal purposes. Its presence may be detected by treating an alcoholic solution of creosote by a test solution of barium hydrate. If coerulignol is present the solution will turn blue or show a bluish tinge. Benzin may be substituted for alcohol with the same result. The United States Pharmacopeia has adopted this as one of the tests indicating the suitableness of a specimen of creosote for medicinal use.

I have referred to the early studies of creosote by its discoverer, Reichenbach, in order to bring into marked prominence the fact that it was first obtained from tar from the beech wood, and the early experiments made upon this agent, not only chemically but also physiologically and clinically, were made with the form of creosote which is still considered the best for medical use and which is now used almost exclusively in therapeutics. An analogous substance obtained from coal-tar is simply a mixture of phenol and cresylol of variable composition, or in other words an impure carbolic acid. These differ, chemically, principally in the following characters: Creosote from wood-tar added to an equal quantity of glycerin is precipitated upon the addition of water; added to collodion it does not coagulate it; and when treated with nitric acid and heat, by Clarke's method, yields oxalic acid. The so-called creosote from coal-tar is not precipitated by water from its gelatin solution; it does coagulate collodion, and yields picric acid when treated with nitric acid. There are corresponding and equally well marked differences between the two compounds in their physiologic action, the most important being the comparative innocuousness of pure wood-tar creosote, which can be taken in large doses, not only without toxic symptoms, but with decided therapeutic results, 500 drops daily having been taken without ill effect.

It has unfortunately occurred that, for many years, the coal-tar extractive was frequently dispensed for creosote, and the latter consequently fell into disrepute for a time on account of the accidents and untoward results from its use. Creosote, according ro Dr. H. C. Wood, is also liable to be adulterated with eupion. In the latest edition of the "United States Dispensatory," by Professors Wood, Remington and Sadtler, the statement is made that "Commercial creosote almost always contains carbolic and cresylic acids from coal-tar, and indeed, much of what is sold for creosote is nothing more than impure carbolic acid." I can not, however, agree with these distinguished authorities in the statement contained in the sentence immediately following the above, which says, referring to carbolic acid, that "this acid strongly resembles creosote, and this resemblance probably extends also to their therapeutic effects, so that the substitution is less to be regretted than might otherwise be the case." This I regard as a most misleading and dangerous teaching. A patient may take as much as 600 drops of creosote, as in Dr. Freudenthal's case (*Medical Record*, 1892), and recover practically without the use of any remedies; but would this case have resulted so favorably had the same quantity of carbolic acid been swallowed instead of creosote?

The principal constituent of creosote is guaiacol, the methyl ether of pyrocatechin, which is present in the proportion of 60 to 80 per cent. in the best specimens. Guaiacol in a pure state is crystalline, but as commonly met with is an oily-looking fluid with a peculiar pungent, smoky odor. It can be obtained, however, in an absolutely pure condition from a commercial sample, by cooling with a mixture of ice and salt and then separating the crystals which have formed, as stated by S. Winghoffer (*Pharmaceutische Zeitung*, Berlin, 1894).

On account of the liability to adulteration in commercial guaiacol and its variable composition, various compounds have been introduced into the practice of medicine as substitutes for creosote and guaiacol. Among the more prominent of these are the carbonate of guaiacol, guaiacol salol, benzyl-guaiacol or benzosol, cinnamyl-guaiacol or styracol, guaiacol phosphite, guaiacol biniodid, and most recently the guaiacol valerianate. These various compounds are administered with the view of their undergoing decomposition in the intestinal tract and yielding guaiacol at the point where it can be most readily absorbed into the blood vessels. In this way the administration of chemically pure guaiacol is accomplished more surely than by any other method. Moreover, these compounds, generally speaking, are more agreeable to the palate than the guaiacol itself.

Physiologic action.—Locally, guaiacol acts, like solutions of carbolic acid, to produce limited surface anesthesia. Dr. Newcomb of New York, at the recent meeting of the American Laryngologic Association, recommended a 5 per cent. solution in olive oil as a substitute for cocain for nasal operations. I have used the guaiacol valerianate for this purpose both in full strength and diluted, and found it to produce, after slight sensation of heat, decided anesthetic effects which are slower in appearing than after the application of cocain, and which are not followed by secondary hyperemia. The antiseptic power of guaiacol is also of great value in throat and nose operations. We know of the frequency of the presence of virulent bacilli in the nasal chambers of apparently healthy individuals, and the routine use of detergent remedies followed by a decided antiseptic, such as guaiacol in oily solution, or the more agreeable valerianate of guaiacol, is now almost necessary in the conduct of our hospital and private work. I should have stated that the valerianate has a strong odor of valerian which almost masks the guaiacol, and produces a combination suggestive of walnuts. Guaiacol valerianate is a local anesthetic to the skin when applied in full strength. The temperature-reducing power of guaiacol, discovered by Sciolla[1] in 1894, is one of the most remarkable observations in the whole realm of pharmacology. This is not likely to occur in persons of good health with a normal temperature, but it is very marked in conditions of pyrexia. Caporali[2] has found that the external applications of guaiacol not only relieve pain and reduce abnormal temperature, but also increase the utilization of albuminoids by the organism and the absorption of fat, and diminish oxidation.

Administered internally, guaiacol and creosote both exert a powerful antiseptic action on the contents of the alimentary canal. The temperature reduction appears to be due to a special action of guaiacol upon the peripheral end-organs of the nerves in the skin and mucuous membranes. Upon the heart and blood vessels there are no obvious effects from moderate doses of creosote or guaiacol. In larger doses it acts as a cardiac depressant, producing diaphoresis from relaxation of the blood vessels, also giddiness and a tendency to fainting or collapse, convulsions or coma, but these disagreeable effects are more likely to occur from commercial creosote or guaiacol than from a chemically pure article. In escaping from the blood by the bronchial mucous membrane and urinary organs, guaiacol exerts a local stimulant and antiseptic action.

From the very brief review of the physiologic action of guaiacol, I turn to the therapeutic use, confining my remarks to the guaiacol valerianate and creosote valerianate, which were recently introduced by Dr Gustav Wendt of Berlin, and which I have used, to some extent, for the past three months in private and dispensary practice. I will simply summarize some of the results of the use of these agents. Both of them are liquid and have a characteristic odor, the guaiacol valerianate being more agreeable to patients than the creosote compound.

In painful affections of the skin, attended by hyperemia such as inflamed acne, or abscess in the external auditory canal, pin-boils, etc., applications of pure guaiacol valerianate relieved pain, and checked further pus formation. In chilblains this agent promptly relieved the annoying symptoms. Small compresses wet with guaiacol and applied over the painful spots of Valleix, afforded almost immediate relief in neuralgia.

In an acute erythema of the face, apparently erysipelatous, but possibly the result of rhus-poisoning, a single application of this agent for ten minutes, followed by applications of zinc ointment containing creosote (one drachm to the ounce), afforded immediate relief and prompt disappearance of the inflammation. In the cases of children, however, or where larger areas are involved, the antithermic effect should be borne in mind, and not more than 25 to 30 drops applied at one time.

I have already alluded to the use of guaiacol valerianate in the treatment of affections of the nose. In acute rhinitis it should be diluted with three or more parts of oil of sweet almonds, or liquid albolene, and in this form it acts as a protective as well as an analgesic and antiseptic application. In chronic rhinitis, especially the purulent form, as well as in some varieties of atrophic rhinitis, it is used in full strength with advantage, as many of these cases are kept up by the presence of virulent micro-organisms, the action of which is inhibited by the guaiacol. In ulcerated conditions, even of supposed tubercular origin, a few applications of pure guaiacol or creosote valerianate materially promotes the healing process, at the same time relieving pain. This observation also applies to the larynx. I have not yet employed it in lupus, but it might be of service here for its local anesthetic effects, prior to scraping and the application of lactic acid and the subsequent use of a 20 per cent. guaiacol spray as recommended by Dr. P. Watson Williams.[3] In tuberculosis of the air-passages, external applications of pure guaiacol have been recommended by Prof. J. Solis-Cohen, and for this purpose the valerianate would have an especial advantage. Internally guaiacol valerianate is given either in milk, in dilute alcohol, or better, in the form of capsules. It checks bronchorrhea and reduces the number of tubercle bacilli in the sputum, at the same time that it tends to prevent re-infection from the intestinal tract. It is well borne in moderate doses, 10 to 30 minims daily, or one to three capsules, each containing 2 grains, or 3⅓ minims, three times a day.

[1] Cronica di Clin. Med. di Geneva for 1892, Vol. p. 171.

[2] Riforma Medica, Naples, No. 175, 1894.

In the treatment of gastric catarrh, chronic gastritis with gastrectasia, and other conditions associated with, or producing fermentation of the contents of the stomach, I have used creosote valerianate in preference to the guaiacol as I believe it to exert stronger antiseptic action. It also overcomes nausea and in connection with lavage, favors the return to healthy condition of the mucous membrane and the re-establishment of appetite and normal digestion.

Fifty years ago, Dr. Fahnestock [4] used pure creosote as an application to erysipelas, with remarkable success. I have already referred to the use of guaiacol valerianate as a local application for erythema and would suggest its use as a topical agent in erysipelas, and also in smallpox.

In cases of pulmonary phthisis the remedy has been well borne, but I have had it under observation too brief a time to report decided results. Very favorable results, however, have been observed by Dr. Rieck of Bassum, Germany,[5] who reports increase of appetite and powers of digestion, and of physical strength under its use. In cases of the initial stage of tuberculosis of the lungs, this improvement was quite marked, with a decided diminution of the cough; the expectoration not only became more free, but it also decreased steadily in quantity. The night sweats disappeared. His report was based on the study of twenty-three cases (sixteen of catarrh of the apices and seven of developed tuberculosis), which were markedly benefited.

I have found the guaiacol valerianate of decided value in the treatment of the so-called catarrhal state which is sometimes considered as the pre-tubercular stage of phthisis pulmonalis. It seems especially suited, when properly diluted with some bland oil, for intra-tracheal injection in cases of advanced phthisis, with or without ulceration in the larynx, or cavity in the lung. Inhalations of creosote in combination with oil of pepermint is claimed by Dr. Carasso, to cause a disappearance of the tubercle bacilli from the sputum, and he reports good results clinically after nearly ten years experience with it. Certainly, the form of aerial medication is worthy of extended trial, and guaiacol valerianate would be preferable to creosote for this purpose. I am of the opinion that we have in guaiacol the best remedy known at present to counteract the pernicious activity of the tubercle bacillus, and I may repeat the words of Dr. Jacobi: "No one treatment of all forms of tuberculosis ever satisfied me to the same degree as has that of guaiacol." When introduced into the stomach, the guaiacol valerianate is decomposed and the effects of pure guaiacol, with the sedative action of valerianic acid, are simultaneously obtained, which may be expected to have a favorable effect on the nervous manifestations of the disease, reducing cough and restlessness. In pneumonia, Malderasco used applications of guaiacol to the thorax posteriorly, over the affected area of the lung, with reduction of temperature and a diminished mortality.

For further and more detailed information, I may refer those interested to reports from the medical clinic of the Royal Charity Hospital of Berlin, by Dr. Grawitz, and Dr. Rieck already referred to, which have appeared in the *Deutsche Medizinal. Zeitung* and the *Therapeutische Monatsheft* for 1896.

DISCUSSION.

A visitor stated that he had examined several specimens of creosote last year and had not found them to contain any guaiacol whatever.

Dr. WOODBURY said that this confirms the statement in the Dispensatory that commercial creosote is often merely impure carbolic acid.

MEDICAL BOTANY.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WILLIAM TRELEASE, Sc.D.
DIRECTOR OF THE MISSOURI BOTANICAL GARDEN.
ST. LOUIS, MO.

Prior to emergence from its nameless barbaric state, the human race was undoubtedly versed in botany of a strictly practical kind. All omnivorous and vegetable feeding creatures distinguish between wholesome and poisonous plants. Even the butterfly selects the right species on which to deposit its eggs, often from among others that to our eyes are almost identical with it. As our race has advanced in civilization, owing its progress to a more and more rigid division of labor, with the attendant and ever increasing specialization by which each piece of the great machine does its work more perfectly, yet more and more completely loses its direct touch with all but a few of the other parts, most men have lost much of what was at first common to all; and this is, perhaps, quite as true of a knowledge of plants as of anything else. As we go from the higher to the more primitive civilization of the present time, we approach by successive steps toward what was at one time characteristic of the entire human race. The country boy has names for most of the plants that the city boy passes by perhaps with a vague notion that they have no names, and he knows abundant uses for many of them. Many is the time that I have hunted sweet cicely and pipsissewa, wintergreen and sarsaparilla in the Connecticut woods; and hoarhound and boneset, yarrow and wormwood are still to be found in the kitchen or the attic of most New England farmhouses. In less favored parts of the globe, where the farmer is a peasant, and the peasant often little better than a clodhopper, this sort of knowledge is even more extensive and widespread.

It is said that the mongoose, when bitten by a cobra, runs at once into the jungle and seeks out a plant which it recognizes and eats as an antidote. Whatever the actual knowledge and its value may be, it is certain that every primitive community believes in the healing virtues of many plants and makes use of them for these supposed virtues; and this sort of knowledge was undoubtedly the first that came after the power of discriminating between plants that are edible and those that are not. Among many people considerably removed from the aboriginal state, even today, the only conception of a collection of herbarium specimens is that they are for some medicinal use.

---

[3] Medical Annual, London, 1897.
[4] American Journal of the Medical Sciences, 1845.
[5] Deutsche Medizinal. Zeitung, Berlin, Dec. 24, 1896.

Recently in turning to the periodical cases in our library for a reference, my eye fell on a nearly forgotten volume of the *Botanic Advocate*, published in New Haven in 1843, and on opening it I found it to bear the legend: "The tree of life yielded her fruit every month, and the leaves of the tree were for the healing of the nations." The journal was published by the Connecticut Botanic Society, and I observed that it contained a series of three articles on the subject assigned me, "Medical Botany," the titles of which were "Lobelia Inflata," "Capsicum Annum" and "Myrica Cerifera." Lobelia and calomel were mentioned on nearly every page and appeared in the titles of many of the articles. It is probably unnecessary to say that the journal and the society of which it was the organ were Thomsonian! Independently of the herbalists, however, the botanists of a generation or two ago were physicians, and M.D. today is not an uncommon suffix to the name of a botanist, so that the subject assigned to me would seem to be an especially appropriate one for a gathering of medical men.

A very large part of the remedies applied by the physician today are of vegetable origin, and this branch of materia medica is an important part of the course of study of a physician. But this, as above said, is the age of specialization; it is the age of druggists and prescription clerks, of triturates and fluid extracts, and of laboratory synthesis. Few, indeed, are the physicians who can make a tincture or an alkaloid salt as well or as cheaply as the druggist or the manufacturing chemist, and, under needful restrictions, the latter are turned to by the physician as certain to supply the things needed in a pure and assimilable form, and in any desired proportion. Even water for the physician's use, that was first employed [illegible] it came from the well, the cistern or the brook, then [illegible]ed before use, and then turned over to the drug[illegible]ist for distillation, so that it could be procured in a pure and safe form for critical purposes, is finally coming into the hands of people whose exclusive business is the distillation and purification of water. The materia medica, like one's clothing, is more and more something to be ordered outside rather than a legitimate subject for home manufacture.

And so it has come that the study of medical botany has today fallen to the pharmacist to a larger extent than to the medical student. He, indeed, is expected to know his botany well. He need not be a vegetable physiologist or a mycologist, and karyokinesis may possibly be a process of which he never heard, but in certain lines he must be a botanist. As a result, we find studies of this kind omitted from the medical curriculum proper and given place in that branch of medical study which has come to have a name and a place of its own—pharmacy.

Whether taught in the medical school or the school of pharmacy or the school of botany, the knowledge which the collector and the manufacturer of drugs needs is of the most practical and useful character. A knowledge of the affinities of plants will very often lead the manufacturer to experiment with species related to those which yield useful products. You are all familiar with the various cinchonas and their relative quinin-producing properties. But in the main the knowledge which is needed is that which enables one surely to distinguish one certain plant in all its forms from all other plants. Every few years the drug trade is exercised over substitutes offered more or less honestly by collectors and jobbers. It is only a short time since cascara sagrada, the bark of *Rhamnus Purshiana*, was replaced very considerably by the bark of a related species, *Rhamnus Californica*, the latter of much inferior quality. It is also only a few years since the trade journals contained an extensive description of the substitution of the roots of *Polygala alba* for the senega snakeroot, *Polygala Senega*. Not many years ago, a sample of tansy which was submitted by a large wholesale house proved, probably as the result of a clerical blunder, to be pansy.

The direct solution of problems of identity like the preceding is the closest link between botany and pharmacy, the most obvious medical botany. It is a branch of the study of vegetable pharmacognosy. The last instance mentioned is a very simple one. The merest tyro could detect the mistake and guess pretty closely at the cause for it; but in the other cases a discrimination between the things to be compared proved decidedly more difficult.

As they come to the wholesaler and the manufacturer, drugs are apt to occur in the form of more or less fragmentary root, rootstock, bark, leaf, flower, fruit and seed. Only rarely, as in the case of opium, are the active principles collected to any great extent freed from the parts of the plant which produces them. Hence, in the great majority of cases, the medical botanist is expected to accurately name certain parts of fairly well-known plants.

It has, unfortunately for this purpose, been the habit of descriptive botanists to aim at as brief a diagnosis of each species as possible, and to use those characters which most surely and most readily serve to separate it from its congeners; or else, as is the case with much modern work, what are felt to be the less variable and consequently the surest and most permanent characters have been taken as the basis of classification, many of the more obvious features being left entirely undescribed. The result is that a person who uses the ordinary manuals of botany, unless he is quite expert as a botanist, requires flowering or fruiting specimens as a preliminary for the determination of their names, and very much of the botany taught in schools and colleges, being based on and preparatory to the use of these manuals, is confined to a study of the characters employed in them.

Medical botany, if well done, must start from a somewhat different standpoint. It by no means follows that a plant which can be determined by aid of the usual manuals only when it is represented by perfect flowering and fruiting material, can not be known with almost or quite as great certainty when neither flowers nor fruit are present. Except in certain genera, like the oaks and plums, the trees and shrubs of our flora may be known with quite as much certainty in the winter when destitute of flower and fruit, and even foliage, as in the summer season; but in the absence of manuals based on their winter characters, this knowledge is possible only as the result of individual observation and investigation, based primarily on a knowledge of the species derived while their summer characters are present; and the same is true, to a greater or less extent, of all of the fragmentary, or as the botanist would call it, imperfect material that passes through the hands of the medical botanist.

The characters which the latter makes most use of are histologic characters. Where sufficiently large fragments of root or rootstock, leaf or fruit or seed occur, these may of course be used, being subject to whatever preparation is necessary to bring them into a condition fit for comparison with either living or preserved authentic specimens; but it is only exceptionally that a superficial comparison is sufficient. Usually the distribution of the woody tissues and ducts and of the bast fibers within the specimen, the occurrence of resin passages, oil cells or latex tubes, the character and the distribution of stomata and palisade cells in the leaf, the occurrence or absence of pubescence and superficial glands, and the structure and grouping of the hairs and the structure of the seed shell have to be looked into. Sometimes, also, it is necessary to test the degree of lignification of certain cell-walls, to determine the nature of secretions, and to examine, both morphologically and chemically, the starch contained in the specimen, which is compared in each of these respects with authentic standards.

Evidently this practical botany of medicines rests upon a more or less intelligent conception of botanic classification, but is itself the application of a special skill. Quite recently a professor of pharmaceutic botany in one of the leading colleges of the country published a laboratory manual which may be held to represent his ideas as to what should be taught in preparation for it. A general knowledge of the parts of the plant, root, stem, leaf, etc., and of each of the principal tissues of the higher plants, is accompanied by a rather thorough examination of several plants of medicinal value or related to medicinal species. As thorough a knowledge as may be of a few plants is sought for, instead of a little knowledge concerning a great many, in the expectation that on this the student will subsequently build an equally thorough knowledge of all of the plants coming within the range of his observation. Not many years since another successful teacher of the same subject laid down the essential thing as being "that the course should be sufficiently comprehensive to equip the student if he desires at its conclusion to pursue further investigation of the study by himself, that is without all assistance other than books such as manuals, class-books, floras, etc." To accomplish this he divides his classes into sufficiently small sections to place specimens of each subject taken up in his lectures into the hands of all pupils, keeping before their eyes at all times on the walls of the room, a carefully labeled set of specimens illustrating the same things, and closing his course by an exercise in which a lot of mixed, unnamed material is placed on the lecture table and sorted out by the professor and students, the characters utilized being indicated step by step during this exercise.

Here, if anywhere, object teaching is essential, and each of these courses is taught as a series of object lessons. Gross characters are made out by the aid of the naked eye and simple magnifying glasses, but for others the compound microscope is brought into requisition and some of the pharmaceutic schools have as a part of their curriculum a regular course in microscopy. Unless it be biology, no word is more abused than this; but for our purpose a sufficient working knowledge of the optic and mechanical parts of the microscope and ability to make serviceable temporary and permanent preparations, is treated as of far greater value than the ability to resolve difficult test objects and to run an unimpeachable ring of Brunswick black or shellac. All that is useful in the technique of the zoologist, the botanist and the embryologist, is utilized to get serviceable sections cut with intelligence at a point calculated to show representative structure, and the skill of the chemist is made to yield, under the cover-glass, reactions as characteristic in their way as those obtained in the test-tube or before the blow-pipe. Equipped in this way, the student is able to determine those characters afforded by his material which enable him to say with certainty that it is or is not the same as a standard specimen of the thing to be compared with. Primarily he is called on to recognize this identity or difference in comparison with the plant that the material is supposed to represent. If it be different the question as to what it really is is only a secondary one, and as his knowledge increases he becomes more and more able to answer these accessory questions.

A good description is more available for use than a poor specimen, and the time is coming when this, as well as each other branch of technical botany, will be equipped with manuals employing the characters which are available in the class of material that must be studied. Perhaps the progress of American systematic botany has been retarded more by the easily acquired habit of naming new specimens by matching them in the herbarium than in any other way; and the best workers, now that monographs are increasing in number, turn first to a monograph and determine a specimen by the aid of the descriptions before going to the herbarium. But what is a good description today may be a very poor description five years from now, owing to the discovery of new material influencing the limitation of species. Hence a specimen is always potentially better than a description, since the former is the thing itself, while the latter is only a more or less subjective interpretation of it, and in medical botany, as in general botany, the herbarium is of prime importance.

The medical or pharmaceutic herbarium should differ from the general herbarium in containing only medicinal plants and their nearest allies. One familiarizes himself with an herbarium of a thousand sheets where he is utterly at sea in a collection of a quarter of a million specimens. The specimens contained in this technical herbarium should be perfect from all points of view:—good in the sense of the ordinary botanist as representing the technical characters which he uses in classifying each plant; good from the standpoint of the person who does not know general botany in representing every part of the plant which he may find in a disconnected condition and wish to compare; good from the standpoint of the histologist as affording usable material for sectioning and microchemistry; and good from the standpoint of the investigator in offering abundant material for study and comparison. Where the woods can be turned to by the student the herbarium specimens are easily supplemented when needed by freshly gathered material; but manufacturing pharmacists, like other manufacturers, drift into large cities where this is often inconvenient or impossible. Not long ago it was said in one of the leading druggists' journals that "the pharmaceutic profession more than almost any other, is inte. [illegible] osition to establish a great botanic [illegible] to the then proposed New York [illegible] tific principles become more and more extensively incorporated into the practice of pharmacy, there is increased recognition of the necessity for a practical acquaintance with the sources of our drugs. This does not of necessity imply an extensive knowledge of theoretic botany, desirable as that is, but a thorough personal acquaintance with medicinal plants is of the greatest value to him who must daily discriminate against substitutions, adulterations, inferior varieties and collections and deteriorated samples. The ideal opportunity for cultivating this acquaintance is in the botanic garden, where we have brought together for immediate comparison the doubtful species under consideration in a living state, and where the characters thus observed can be followed up closely in the herbarium and materia medica collections forming adjuncts to the garden." Besides what can be preserved in the herbarium proper and the garden, the reference collection ought to contain standard material of all drugs in their crude form, so that any changes in appearance which the specimen under study may have undergone during its preparation will be likely to be matched by a corresponding change in the standard; and besides the museum material here referred to, which is most readily utilized by the investigator if kept boxed in immediate connection with the herbarium sheets, a set of histologic preparations ought to be made, representing not only the tissues of each officinal plant from authentic specimens, but also such preparations as can be made from the fragmentary drug, of which good sections are often obtained with difficulty, while the mode of fragmentation is sometimes characteristic.

Today nearly all students are taught not only to observe, but to record their observations, both in writing and by means of sketches. The medical botanist, perhaps more than most others, is likely to be benefited by forming this habit. A sketch made while the study is fresh in one's mind, somewhat idealized, not by the introduction of fanciful details but by the omission of confusing structures which one sees in all preparations, renders the future examination of a slide much easier and the conclusion drawn from a comparison with it more certain. I should therefore sketch the essentials of every preparation so preserved, and while the matter is fresh in one's mind a brief memorandum is easily written in connection with the sketch, describing differences between related things that may be transient in the slide or liable to be overlooked.

Medical botany, therefore, as a technical study for the *manufacturing pharmacist and collector*, and to a less extent for the dispensing druggist, but hardly for the medical man, in my mind is really a minute acquaintance with each plant used in medicine, with each of its parts in the form in which they are employed for the extraction of the drug as finally used; and it is properly learned by a course of study limited to very nearly the lines sketched above. Having reached this point, the botanist very properly, if time permits, extends his knowledge of general botany. Before this point, if he know the meaning of a generic and a specific name, of a natural family and a variety, he is enough of a botanist to do his work well.

To the physician of today, medical botany, which only a few years ago seemed to be passing from his hands, is returning in twofold form, but it is doubtful if the great majority of physicians are justified in dipping very far into it. Occasionally poisoning by eating certain toadstools, or roots of a few umbellifers, demands a certain amount of botanic knowledge, but I take it that in practice the suspicion of this poisoning is as practically useful as the actual knowledge of the plant which has caused it. The dermatologist, more than the general physician, is called on to recognize causes for dermal manifestations which he often traces to the use of food of one sort or another, which in some cases the idiosyncrasy of the patient reacts to in rather a marked way, and it is only a few years since a professor in the Harvard Medical School published an exhaustive treatise on the plants which produce such effects. A few plants, like the poison ivy, are very pronounced external irritants. But so far as practical purposes are concerned, the physician needs to know to what to ascribe certain manifestations of this sort, very much as he needs to know the effect of certain drugs, rather than to have a botanic knowledge of the irritant.

With the growing knowledge of bacteria, however, a more directly necessary branch of medical botany seems to be opening up. It is not necessary for the physician to know all bacteria, perhaps hardly necessary to know any large number of pathogenic species; but tubercle, leprosy, cholera, and certain other diseases of frequent occurrence, are so clearly marked by the occurrence of bacteria in or about the diseased tissues, that a diagnosis is often made with certainty only after a bacteriologic examination has been made. The Widal test for typhoid fever now has come into general use, and in the case of cholera and diphtheria it is, I believe, generally recognized that an easily made pure culture of bacteria from the patient affords the surest and quickest information as to the positive occurrence of the disease.

Today I suppose that there is not a good medical school in the country which has not a well equipped bacteriologic laboratory. The teaching needed for this branch of medical botany, like that needed for the older medical botany, which is now more properly regarded as pharmaceutic botany, ought to be of the most directly practical kind. A knowledge of methods first and of facts afterward is what is demanded. Some bacteria, the ordinary aerobic species, are so easily isolated and grown in pure cultures that the means of doing this ought to be at the hand of every physician, though I observe that certain boards of health are now undertaking to supply the apparatus and culture media needed for diphtheria work, so as to reduce the practitioner's part to the minimum of manual manipulation. The preparation and examination of slides offers little difficulty to the medical student who is already equipped with a knowledge of microscopic and histologic technique, so that he readily learns the special treatment needed for this sort of work. Here, as in pharmaceutic botany, the reference to authentic descriptions and authentic material becomes more and more necessary in proportion as one passes from hasty diagnosis to scientific investigation; but just as the dispensing druggist is becoming more and more freed from the routine of botanic examination, so the exhaustive study of the etiology of any germ disease is passing more and more from the physician to the medical bacteriologist who specializes in this direction, and whose training, built on a broad clinical experience, is supplemented by a continuation of the preparatory studies which the ordinary physician is obliged to make. The difference is in degree, however, rather than in kind.

DISCUSSION.

Professor **Remington**—The subject of botany itself, except the coarser structure of plants and bacteriology, has passed from the curriculum of the medical colleges and is now taught as a primary branch in the pharmacy colleges. I think that there is very little probability of the restoration of medical botany to its former place in the medical school; but it is well to know that it is taken up in other schools.

Dr. **Paquin** of St. Louis—The great difficulty in regard to the study of botany by medical men is want of time, but this must be provided for, as bacteriology is going to develop enormously in the near future.

PHARMACEUTIC CHEMISTRY, PHARMACOLOGY AND PHARMACO-PHYSICS THE NATURAL STEPPING-STONES TO SCIENTIFIC MEDICINE.

Presented in the Section on Materia Medica, Pharmacy and Therapeutics at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, Pa., June 1-4, 1897.

BY ALFRED R. L. DOHME, Ph.D.

BALTIMORE, MD.

Before entering upon a discussion of the subjects embraced by all the above caption, it might not be out of place to make clear what the exact meaning of the terminology that will come up for consideration is. Some little confusion has arisen recently, because of the double use of the word pharmacology, and the dictionaries do not help us out in the matter. They define pharmacology as the study of drugs both as to their recognition, properties and therapy. In other words, it is a general term for the study of drugs and their therapy, or a combination of pharmacy, the science of compounding drugs, with materia medica, the description of drugs and their medicinal effect. This is in accordance with the derivation of the word, which is made up of the Greek words, *pharmakon* and *logos*, meaning a discourse on or a study of drugs. However, the word has also been used, especially in Germany, to mean the study of the physiologic effect of drugs on the human system. Thus, when acetanilid is taken into the stomach and produces certain results or effects, it is the province of pharmacology to study and explain what organs, tissues, fluids, etc., of the body are affected by the same and in what way. Pharmaceutic chemistry has to do only with the chemistry of drugs, *i. e.*, given a drug, say belladonna root, it is the province of pharmaceutic chemistry to discover entirely what the same contains and in what relative quantities, thus: atropin, hyoscyamin, hyoscin, starch, resins and which, fats and which, malic acid, etc. Pharmacognosy is the study of the various physical properties of drugs which will enable one to recognize them, including their history. It hence embraces their botany, microscopy, histology, the chemistry of their constituents and the history of their use as a drug. Pharmacodynamics is a term that has been employed to express the effect and uses of medicines, being derived from the Greek words *pharmakon*, a drug, and *dynamikos*, the power or effect, and is hence practically the same as therapeutics. In considering the study of the effects of drugs upon the human economy, it appears to me that we have to become acquainted with the following facts in order to get at a scientific knowledge of how drugs act. We should know all the constituents of the drug we desire to use; we should know the physiologic effect of every constituent of the drug we are administering and, then, use only those constituents, or preparations containing only those constituents that produce the effect we desire to produce; and we should know the cause of the effect of each of these constituents. The first embraces the pharmaceutic chemistry of the drug, the second its pharmacology and the third its pharmaco-physics, which last word I have coined, as I believe there exists no word to express the study of the causes of the effects of drugs. It would be well to make clearer, perhaps, the distinction intended to be conveyed by the terms pharmacology and pharmaco-physics, and a concrete example will best serve to do this. Let us take acetanilid, as this will serve our purpose quite well and is besides one of the most generally used drugs. The pharmaceutic chemistry of acetanilid is the study of its formation, properties and decompositions. Its pharmacology is the knowledge resulting from the study of its physiologic effect on all the organs, tissues, fluids, etc., of the body, thus making plain what effect it produces, when we administer it, on the heart, blood pressure, nerve centers, liver, kidneys, mucous membranes, blood, lymphatics, etc. Its pharmaco-physics is the knowledge resulting from the study of the cause of the effects observed in studying its pharmacology, and would represent the study of the physiologic effects of all the groups contained in the acetanilid molecule. Acetanilid is made up of the group of acetic acid or acetyl (CH_3CO) and anilin ($C_6H_5NH_2$), which in turn is made up of the ammonia radical, amid (NH_2), and of benzene (C_6H_6), a hydrocarbon produced by the destructive distillation of coal. The province of pharmaco-physics would be to discover whether the effects of acetanilid, which we observed in studying its pharmacology, were due to the acetyl group, the ammonia group or the benzene group; or, what is more probable, which of the various effects of acetanilid was due to each and all of these constituent radicals of the acetanilid molecule. This can be done very readily by varying the various radicals and observing the failing or modification of this or that effect. Thus, if the red corpuscles are precipitated, producing cyanosis and eventual collapse, is this due to the ammonia radical (NH_2), or the acetyl radical or to the benzene radical, present in the molecule? Further, if the blood pressure is diminished, to which of these radicals is this due, etc.? If this is tabulated and known, for the various drugs of our pharmacopeia, we will reach such a desired and advanced stage in our knowledge of medicines, that we can control the unpleasant and undesirable effects of our remedies entirely and produce and use only such remedies as will produce just the effects we desire and no other effects. This is not only true of synthetic remedies but of all remedies, inorganic as well as organic. No doubt this appears chimeric to many and beyond the limits of probability and also usefulness, because of its apparent complexity, but there can be no doubt at all that it is not only among the probabilities, but that it is the natural evolution of the science of medicine that will take place in the next fifty years. German schools of medicine are entering upon this enormous and as yet untrodden and fertile field of investigation, and we should give it the attention that its importance merits. It is not a matter that can be taught, because it is as yet an unknown or practically unknown science, but it can and should be made the subject of investigation and study, so that we may become acquainted with the facts that it will give us, and enable us to make use of them in administering medicines. How few physicians today know the exact effect of the medicines they prescribe on the various organs, and what is the cause of that effect? They know that jaborandi produces activity of certain glands, resulting in increased secretions thereby, and they know that the pilocarpine in these leaves produce this effect, but do they know what other effects pilocarpine produces on the other organs, say on the blood, liver, kidneys, etc., and do they know what causes pilocarpine to produce this effect? They may say that it is not necessary for them to know this, as the effect is produced just the same and that is all they desire. This is quite true, and in the present state of our knowledge of medicines and their effects it is about all they can know; but would their ability to combat disease and administer medicines more scientifically and effectively not be many times increased if our knowledge of these same medicines and their effects and the cause of the effect, were known to them. They would then know that since, we will say for example, pilocarpine interferes with the functions of the liver it is not advisable to use this drug for a patient who requires a diaphoretic, but at the same time has a diseased liver. We might perhaps have learned by that time that a certain radical in the pilocarpine molecule produced the untoward effect on the liver, but that pilocarpidine, while still an effective diaphoretic, no longer produced this effect on the liver, due to the elimination from its molecule of the undesirable radical present in the pilocarpine molecule. There can be no doubt of one thing, and that is that medicine in its narrow sense, *i. e.*, the science of the administration of drugs, has not advanced at the same rate that the sciences of surgery, bacteriology, pathology or anatomy have during the last half century. In fact, many physicians have grown skeptical as to the value of drugs and think the less of them used, as a rule, the better. The development and future above outlined for the science of medicine in its narrower sense, will, unquestionably, remove all such skepticism and push therapeutics forward as a most necessary and invaluable requisite for the combating of disease. I may be pardoned when I say that scientific medicine, *i. e.*, the scientific administration of drugs, is only in its infancy at present, and that most of our medicines are administered empirically, *i. e.*, are administered not because we know exactly why they are what our particular case in hand calls for, but because experience has taught us that they are effective and will produce certain results. I do not wish to be misunderstood in this connection, and when I say the administration of medicines is largely empirical I do not mean to state or imply anything derogatory, but merely to say that our present knowledge of the administration of medicine does not enable us to do anything better. My purpose in going into this detail as to empiricism vs. science is merely to explain the meaning intended to be conveyed by the term scientific medicine in the title of the paper I am presenting. All physicians will agree that it is desirable to increase our knowledge of pharmacology and pharmaco-physics, for the more they know about the effects of drugs and their cause the better off they will be in successfully combating various diseases. There is one obstacle, however, to success in this direction in this country and which does not exist in Germany, and that is the indifference or unwillingness of hospital and clinics to take up and try, carefully and scientifically, any new preparations that may be offered them for experiment. The necessary thing to be done in this country to make the development and study of pharmacology successful, is the adoption of courses of lectures on these subjects, together with the opening of laboratories for their experimental study and research. In Germany chairs of pharmacology are established at almost every university, and at several of them the work in the lecture room is supplemented by actual experiments and actual investigations and study in the laboratory and clinic. Thus, the laboratories of Professor Schmiedeberg in Strasburg, Baumann in Freiburg, and Drechsel in Leipzig, are headquarters for this work in Germany, and their number is steadily growing. It has not been so many years ago that in order to study the new science of pathology one had to go to Berlin, to Virchow's laboratory, but Virchow has gradually developed other capable teachers and expounders of his theories and methods, and now pathology is a part of the course in medicine in practically every college in this country. So it will be with pharmacology and pharmaco-physics. The pupils of Schmiedeberg, Drechsel and Baumann will organize laboratories and courses, just as their instructors did, and the result will be that every school of medicine will embrace as part of its curriculum lectures and laboratory work on pharmacology, and perhaps also pharmaco-physics. Some schools of medicine have such courses already, as, for instance, Johns Hopkins, Harvard, Pennsylvania, Ann Arbor, etc., and others will unquestionably adopt the same in the near future. When this is brought about, the era for the scientific administration of drugs, *i. e.*, scientific medicine, will set in, and the stepping-stones to reach that stage will be pharmaceutic chemistry, pharmacology and pharmaco-physics.

THE NATURE OF THE LEUCOCYTOSIS PRODUCED BY NUCLEINIC ACID; A PRELIMINARY EXPERIMENTAL STUDY.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at te Forty-eighth Annual Meeting of the American Medical Association, *Philadelphia, Pa., June 1-4, 1897.*

BY DELANO AMES, A.B., M.D.
Lecturer on Pathology and Director of the Pathologic Laboratories in the Baltimore Medical College; Pathologist and Visiting Physician to the Maryland General Hospital; Pathologist to the Union Protestant Infirmary Hospital.

AND A. A. HUNTLEY, M.D.
Assistant Demonstrator of Pathology in the Baltimore Medical College.

Within the past two or three years there has come into gradual prominence a system of therapeutics known popularly as nuclein therapy, which is attracting more and more attention and receiving a growing recognition at the hands of the medical profession.

The use of nuclein was first advocated on purely theoretic grounds, it being claimed that by its use the germicidal power of the blood could be increased and hence the resistance to diseases of germ origin heightened. Of late, however, certain writers have denied that nuclein acts as it was supposed to, and in consequence, its use being founded on a false conception of its powers, have claimed that it was not beneficial.

The application of nuclein to the treatment of certain diseases, especially to certain of the infectious processes, seems to be attended with beneficial results, though the observations are as yet too few and too incomplete to be of much value. Such as they are, however, they tend to confirm the views on which its use was first advocated and should be taken for what they are worth.

In order to fully comprehend the point at issue, it will be well to briefly review the various steps that have led to the discovery and use of this interesting substance.

Ever since the announcement of the fact that normal blood plasma of man and animals possessed definite germicidal power, endeavors have been made from time to time to determine the nature of the substance that imparted this property to the blood, in the reasonable hope that with its discovery we would be put in possession of the means to artificially increase this bactericidal property at will, which it is readily conceded would be of considerable importance in the treatment of certain diseases.

As early as 1872, the fact that organisms when injected into the circulation rapidly disappeared was observed by Lewis and Cunningham.[1] Similar facts were recorded from time to time by a number of observers, among whom may be mentioned Traube,[2] Fodor,[3] Wysokowicz,[4] Grohmann,[5] Nuttall[6] and others, and numerous theories, which it would lead us too far to mention or discuss at this time, were advanced to account for the apparent destruction of the invading organisms on the part of the body.

No explanation not open to serious objection was offered until the publication of the work done by Nuttall under Flüge. He claimed that the injected organisms disappeared because the normal plasma was germicidal and destroyed them. He gave positive evidence of this fact.

Following the work done by Nuttall, Nissen,[7] also working under Flüge on the same question, came to the following conclusions among others: 1, that normal blood plasma can easily destroy the cholera germ and Eberth's bacillus; 2, that the addition of small quantities of sterilized bouillon or of normal salt solution would not destroy the germicidal property of the blood; 3, that for a given volume of blood there is a maximum number of bacteria that can be destroyed; 4, that blood rendered uncoagulable by the addition of peptone is still germicidal; 5, that blood the coagulation of which is prevented by the addition of 25 per cent. of magnesium sulphate has its germicidal property diminished; 6, that filtered blood plasma from the horse is germicidal.

While, then, it was clearly proved that normal blood possessed certain properties detrimental to the growth and development of bacterial life, it was not as yet shown to what this property was to be attributed. Among some of the ideas advanced may be mentioned that of Behring,[8] who believed that the germicidal action of the blood of certain animals was due to its great alkalinity.

Metchnikoff[9] attributed the ability of the blood to destroy bacteria to the power of certain of the white cells of the blood, the polymorphonuclear leucocytes, to devour the micro-organism, to their *phagocytic* power, as he termed it. That these cells can and do act in this way at times can not be denied, and nothing is more attractive than to watch one of them surround and engulf a malarial parasite in the blood on the warm stage. That the true germicidal property of the blood does not lie in this action of the leucocyte was shown some time after by Buchner, who killed these cells by freezing and then thawing the blood, when its power to destroy micro-organisms was found to be undiminished. Buchner[10] further came to the conclusion, from a series of experiments that it is not necessary to review here, that the actual germicidal substance in blood was its serum-albuminous constituent.

Vaughan,[11] in a paper read before the medical section of the First Pan-American Medical Congress, in 1893, showed positively that this conclusion of Buchner must be erroneous, since it is known that whatever the substance in the blood is that possesses germicidal properties, it is not affected by peptic digestion, while serum-albumin is readily digested, as is well known.

From that time to the present numerous papers on this most important subject have appeared, and as many attempts have been made to clear up the question by the various theories that have been advanced.

It would only be necessary to mention the names of some of the investigators to show that the greatest activity has prevailed in this particular field of research. Among those who have followed Buchner may be mentioned Pruden,[12] Rovighi,[13] Pekelharing,[14] Hankin,[16] Bitter,[17] Christmas[18] and a score of others, each with his own set of facts and consequent deductions. Suffice it to say that to each one there seemed to be some reasonable objection that rendered it probable that the true nature of the germicidal substance remained in doubt up to a very recent date.

Vaughan, in the paper just cited, makes a careful survey of the literature of the subject, analyzes the work of the most important investigators and comes to the following conclusions:

1. That serum-albumin as described by Buchner is not the germicidal substance in blood serum, since it is readily converted into peptone by peptic digestion, and still the germicidal property of the blood is unaltered. Peptone further is favorable to the growth of bacteria and is used in preparing nutrient media.
2. That the germicidal substance must belong to the proteids, otherwise it would be difficult to explain the fact that a temperature of 55 degrees C. renders blood serum inactive.
3. That the only proteid likely to be present in blood serum and which is not destroyed by peptic digestion is *nuclein.*

He then asks the following questions: 1. Is there a nuclein in the blood? 2. Has this nuclein, if present, any germicidal properties?

Without reviewing Vaughan's work, it is only necessary to say that he succeeded in isolating a substance from the blood which is undoubtedly a nuclein, and that he and a number of others have demonstrated the fact that it has very decided germicidal properties. It is therefore safe to say that we may now consider blood plasma to be germicidal by virtue of the *nuclein* that it contains.

Having then reached this important conclusion let us briefly inquire into the nature of this substance. What is nuclein?

The term nuclein was originally applied to a peculiar phosphorus-containing substance which was isolated from pus. Chittenden,[19] speaking of this says, "it was discovered that this or related substances were widely distributed through nature in both the animal and vegetable kingdoms wherever nucleated cells occurred."

From a physiologic standpoint nucleins may be considered to form the greater part of the chemic substance found in the nuclei of all cells, that substance which shows such a strong affinity for certain coloring agents, and which is sometimes spoken of as chromatin. It is, speaking broadly, "that constituent of the cell by virtue of which the histologic unit grows, develops and reproduces itself." It will be readily seen, therefore, that nuclein must be very widespread and that relatively there will be more of it found in those tissues or structures that are the richest in cellular elements.

Chemically, the nucleins are highly complex proteid bodies, of weak acidity, containing a certain amount of phosphorus. They are insoluble in weak acids and in alcohol, but are soluble in dilute alkalin solutions, the action of the alkali being to liberate free nucleinic acid, or to separate it from the albuminous matter with which it is in combination. Thus viewed a nuclein "is simply a combination of some form of proteid matter with a nucleinic acid" (Chittenden[19]). Further, the nucleinic acid can be prepared from any form of nuclear material, but it is found to be most easily gotten from yeast-cells. It is "characterized by its large percentage of phosphorus, as much as 9 per cent. having been found in some forms" (Chittenden). This acid can again be decomposed by the action of dilute mineral acids, and when so treated gives as cleavage products, various kinds of nucleinic bases, the difference depending on the nature of the tissue or substance from which the nuclein was originally derived. Thus, for example. the nucleinic acid from yeast-cells yields, when treated with a dilute mineral acid, four distinct substances—bases, while that from the thymus gland of calves yields only one base—adenin. These facts are mentioned because, as is well-known, there is some close relation existing between this group of substances, the decomposition products of the nucleins, known as "xanthin bases," and the formation and excretion of uric acid, a question that we will not attempt to discuss at the present time.

Since all nucleins contain phosphorus, and since it seems that the greater the amount of phosphorus the more active is the nuclein, the amount of phosphorus which any given sample of this substance contains may be taken as an index of the amount of nucleinic acid present in the preparation.

The various commercial articles now on the market have been found to vary considerably in the amount of nucleinic acid that they contain. According to a recent report of Professor Chittenden,[19] that manufactured by the firm of Parke, Davis & Co., under the name of "Nuclein Solution from Yeast" contains the most phosphorus, and therefore is the richest in nucleinic acid. It is the preparation used by us in the experiments that form the basis of this communication.

Having seen what nuclein is. let us inquire into the nature of its physiologic actions. The use of this substance as a therapeutic agent is of such recent date, and is based on such a narrow margin of known facts regarding its action, that there is comparatively little known as to its full action on the diseased economy.[20] Löwitt[20] some time ago made the statement that, by subcutaneous injection of nuclein in animals in the ratio of 1 per cent. per kilo. of weight, he quickly produced very dangerous symptoms, such as threatened cardiac and respiratory failure. It is impossible to say what preparation he used, or how it was prepared, but most certainly our observations and those of others have been just the opposite, and we have never seen, either in animals or man, any harmful symptoms whatever even from considerable doses. That harmful results might occur if excessive doses were used may be conceived, but the same holds good for nearly every therapeutic agent, each having its proper dose and indications for its use, and there would be no occasion whatever to use doses of this preparation of such size as to produce even the mildest signs of danger. Certain effects have been noted in the treatment of tuberculosis and other diseases, with this remedy, but it is not the province of this paper to discuss these, which belong more properly to a consideration of the therapeutic uses and effects of nuclein. Whatever the other effects may be, however, there is one result of the administration of nuclein, either by the hypodermic method, or per os, that appears to be quite constant, and on which its therapeutic value is supposed to depend in the treatment of the various forms of bacterial disease. This effect is the *apparent production of a leucocytosis.*

It will be recalled that in the opening paragraph we stated that, could that substance be discovered by virtue of which the blood possessed germicidal properties, it might with reason be hoped that some means could be devised by which this valuable property could be artificially increased at will. Since the germicidal property of normal blood resides in a substance known as nuclein, and since this is derived from the nuclei of certain cells of the blood, the white corpuscles, it is believed that by increasing the number of these cells very materially the germicidal power of the blood plasma may be considerably heightened.

We have just said that one of the constant results of the injection of nuclein, or of its administration per os, was the production of an apparent leucocytosis, meaning by that term an actual increase in the total number of leucocytes per cubic millimeter, circulating in the blood. The word "apparent" is here used advisedly because it is claimed by some writers that the increase is only apparent, not real. It can readily be seen that on the determination of this important point the value of this or of any similar preparation will rest. If the results following the administration of nuclein consist only of a re-arrangement of the leucocytes in the different portions of the circulation and not of an actual increase in the number of the same, we can not hope by its use to augment the germicidal power of the blood. since we can not increase those bodies, the white corpuscles, that produce the germicidal substance.

According to those who hold the view of leucocytosis just mentioned, the effect of an injection of nuclein, or of any substance acting as it does, is to cause a determination of the leucocytes to the peripheral circulation and away from the circulation in the internal vessels. How this is supposed to be accomplished we will see later. On examining a drop of blood drawn from the finger tip, or from the lobe of the ear, as is the usual custom some hours after the administration of nuclein, it is found that there is an increase in the number of leucocytes, chiefly, though not entirely, confined to the polymorphonuclear variety, which fact is explained in the way just mentioned, it being denied that the total number of leucocytes is at all increased. According to this view then, what we have been taking for an increase in the number of cells is in reality nothing more than an affair of distribution, and we would have to alter our definition of leucocytosis accordingly.

---

[20] This paper was written before Dr. Vaughan's recent article on the use of nuclein in cases of pulmonary tuberculosis appeared. The authors have themselves used it in a large number of such cases with apparent marked beneficial results. These it is expected will be reported later.

Cabot,[21] in his recent book on the blood, defines leucocytosis as: "An increase in the number of leucocytes in the peripheral blood over the number normal in the individual case, this increase never involving a diminution in the polymorphonuclear varieties, but generally a marked absolute and relative gain over the number previously present." This definition he follows up by the statement that whether or not it be true that a leucocytosis is only an affair of distribution "it is accurate to say that in the drop which we draw (whether also in the internal organs or not) the leucocytes are present in increased numbers per cubic millimeter." This leaves us in doubt as to Cabot's own view, though strongly inclining us to believe that while he has not so expressed it in as many words, he holds the opinion that in leucocytosis there is an actual increase in the number of cellular elements throughout the circulation.

Ziegler,[22] also defines leucocytosis as an increase in the number of white corpuscles circulating in the blood and points out that these may come either from a new production of cells in the cell-forming organs, from a proliferation of the cells in the circulating blood, or further that the increase may under certain circumstances be due simply to the discharge into the circulation, from the lymph glands, of large numbers of ready formed, partly matured cells.

The arguments advanced in support of the view that leucocytosis is but an affair of distribution are worthy of very careful examination. There are two chief ones on which the theory rests. In the first place it is claimed that the apparent increase in the number of cells occurs chiefly in the polymorphonuclear variety which, if we accept Uskow's theory and classification, are the mature elements. If it is true that an actual new formation of cells takes place as the result of the injection of nuclein, the claim is made that we should find the greatest percentage increase in the mononuclear or young elements. In the second place it is claimed that an examination of the blood shows that while there is an apparent increase in the number of cells in the peripheral vessels the central circulation shows a corresponding paucity of cellular elements.

These two arguments, if based on careful experimental evidence, would be very strong indeed and would point to the accuracy of the conclusions drawn. It was partly with a view to clearing up this question that the experiments which form the basis of this paper were undertaken, and we believe that from the results we have obtained, and from those obtained by others, especially by Buchner and Hahn in a different direction, which however bears strongly on the point in question, that we have reason to believe the leucocytosis following the administration of nuclein to be one in which there is an actual increase in the number of white corpuscles in the circulation. To what process this is due we are not able to state, though we are inclined to the view that there is proliferation within the cell-forming organs and probably in the circulation as well.

Before detailing our experiments let us examine more closely the two chief arguments advanced in support of the other view of leucocytosis, that first mentioned.

In examining a drop of blood, drawn, we will say from the finger of a person some hours, or a day or so, after an injection of nuclein, it is readily seen that the white corpuscles are present in increased numbers, and that the largest percentage increase is in the polymorphonuclear variety. This fact can not be disputed, and since, as Ehrlich[23] has pointed out, the blood-cell-forming organs discharge into the circulation only the small mononuclear or young elements, it seems at first difficult to explain the presence of so many of the older mature cells. The question however resolves itself really into one concerning the length of the life-cycle of a leucocyte. How long may it take for a young element to pass through the various stages in its development and become matured? Is it not probable that the mistake has been made in examining the blood too long after the injection of nuclein, so that time enough has elapsed to allow the young elements formed as a result of the injection to mature? If this is the case the first argument advanced loses it weight and becomes in reality an argument in favor of the other view.

In the course of all of our experiments we found that within so short a time as from five to ten minutes after the injection of nuclein there was a noticeable increase in the number of leucocytes in the peripheral as well as in the central circulation, and, moreover, that the greatest percentage increase was not in the mature, but in the young varieties. If it is possible then for an actual reproduction to begin within so short a time as five to ten minutes after an injection, is it not probable that the majority of these elements can pass on to the mature stage after the lapse of a day, or even of some hours? We think it is and that herein lies the explanation of the fact that when a drop of blood from the peripheral circulation is examined some hours after the injection, the increase is seen to be chiefly in the polymorphonuclear forms. The fact, also, that in our experiments we found that the small young elements were the first to be increased in the largest proportion is consistent with the view that the leucocytosis produced by nuclein at least, consists of an actual increase in the total number of white cells, and bears out the statement of Löwitt[20] that following an initial stage in which there seems to be a lowering of the number of corpuscles (which phenomenon we have not attempted to study), there is a development of young mononuclear forms which gradually pass through the developmental stages into mature elements.

Goldschneider and Jacob[24] also, though they disagree with Löwitt in some of his conclusions, support him in the statement that the injection of certain substances produces an increase in the number of leucocytes most noticeable in the mononuclear forms.

Romer[25] likewise takes this view of the process and goes so far as to say that he believes the reproduction to take place within the circulation as well as in the blood-cell-forming glands.

In attempting to explain how it is that the injection of such a substance as nuclein causes a determination of leucocytes to the peripheral circulation and away from the that in the internal vessels, it seems to us that the advocates of this theory disclose its weakness as they do in no other way.

While many writers attempt no explanation others, as Wells,[26] in a recent article states that according to his belief "the key to the whole problem is to be found in the principle known as ch [illegible] more commonly as chemotaxis." According to this author the effect of an injection of nuclein is to exert a chemotactic action, the result of which is the attraction of the polymorphonuclear leucocytes from the central to the peripheral circulation.

We fail to see how such an action could take place, even granting that nuclein possessed chemotactic properties, for is it to be supposed that after being injected subcutaneously the substance will remain in the peripheral circulation? Will it not naturally circulate freely throughout the system? This at least is what one would expect, and doing so it would then exert its chemotactic influence, if it had any, in all portions of the circulation, and the results would be *nil* because the various attractive forces would neutralize one another. In fact, this chemotactic explanation does not seem to us to be any explanation at all.

Aside from all the foregoing facts that seem to us to strongly militate against the idea that leucocytosis is but an affair of distribution there is another fact, well authenticated, that also points conclusively to the incorrectness of this view.

Referring again to a paragraph in the early part of this paper, it was stated that the germicidal property of the blood resided in its nuclein and that the richer in cells a part was, the more its content of nuclein, and by the same reasoning the greater its germicidal power.

Buchner, working on this question, found that fluids rich in cells possessed a greater germicidal power than did the normal blood of the same animal. More recently Hahn,[27] working under Buchner and following the suggestion contained in the above observation, has attempted to increase the germicidal power of the blood plasma by producing an artificial leucocytosis. Hahn found that the blood plasma of animals treated by hypodermic injections of nuclein solution possessed germicidal power considerably greater than the blood of the same animals had possessed before the injections. Had the effect of the injections been to cause a determination of the leucocytes to the peripheral circulation only, and not an increase in the total number of the same it is very difficult to explain Hahn's results which, therefore, seem to us to point very conclusively to the fact that the leucocytosis produced by this substance at least consists of an actual production of new leucocytes, increasing the number of nuclein-producing bodies and in consequence heightening the bactericidal power of the blood.

Among those who are cited by Wells as supporting the view that we believe to be incorrect may be mentioned X. Reeder,[28] who says, "as to the origin of leucocytosis we have on the ground of experimental examinations *no good ground* to believe that it is due to an increased supply of white blood corpuscles from the blood-making organs, still less to an increase of the same in the blood, or to an abnormal collection of wandering cells. It must be considered as more probable that the leucocytosis is based only upon an *insignificant increase* of the entire number of white cells circulating in the blood, in that there occurs an abnormal distribution of the same in the different vessels in favor of the periphery."

A careful examination of this statement of Reeder shows that, while in the first paragraph he states positively that there is *no evidence* of the new formation of white cells *whatever*, he goes on to say in the next that there is an insignificant increase in the total number. He would seem then to admit that a production of new cells could and did take place, even if in small number only, and in so far to contradict himself. If it is admitted that it is possible for a reproduction to take place, why not in considerable numbers as well as in small? The important fact is in admitting that they *can and do reproduce.*

Schulz[29] is also mentioned as an advocate of this view. In one experiment made by this observer, and cited by Wells, he injected into the ear of a rabbit 2 c.c. of bacterial protein and immediately withdrew blood from the other ear, in which he found on counting the leucocytes only 3,300 as against 11,100 before the administration of the protein. As rapidly as possible, counts were made from several internal vessels, the average of which was 21,500. From these figures he draws the conclusion that the decrease and therefore also the subsequent increase, is only apparent, and that at first the leucocytes left the peripheral circulation for the central, and afterward the central for the peripheral. He evidently overlooked the fact, that had he estimated the total number of leucocytes before and after the injection he would have found that in the very short time that it took him to make the experiment there had been an actual increase in the whole number of 1,300 white cells per cubic millimeter, even though the cells at the time of the count were unevenly distributed.

From all the facts that we have cited it would appear that we are justified in looking on the change in the circulation that follows an injection of nuclein as a leucocytosis in which there is an increase in the total number of white corpuscles.

The experiments that we made were all upon medium-sized dogs, and while we will not detail each one we will give the steps pursued and a few of the results which are typical of all, since with very slight variations practically the same results were obtained in all cases. Before putting the dog under ether a count was made of the leucocytes in the peripheral circulation. Ether was then administered and the same was done for the peripheral and central circulations. We made the count of the peripheral circulation before the administration of ether, because we found that the ether alone produced some increase in the number of leucocytes, the amount seeming to depend on the rapidity or slowness with which the animal succumbed to the anesthetic; a greater change was noted in those dogs that struggled the most and required the most ether. After making the counts already mentioned a hypodermic injection of nuclein solution (1 per cent. P. D. & Co.), varying from 25 to 45 minims in the different experiments, was given and counts made from both the peripheral and central circulations every five minutes thereafter up to thirty-five minutes in some cases. Care was taken to allow the animal to bleed but little, and as slight disturbance was produced by the operation as possible.

The leucocytes in the blood withdrawn were stained with a week solution of methyl violet in normal salt solution and the results of the various counts tabulated. In every instance ten counts at least were made and the average taken. The entire field of the blood counter was counted every time. In this way it was hoped to reduce the limit of error as much as possible. The general results of these experiments may be summed up as follows:

1. The administration of ether alone causes an increase in the number of leucocytes over that found in the circulation before its administration. The

amount of the increase seems to depend on the amount of ether used and the time required to anesthetize the animal.

2. Before the administration of nuclein the counts showed that the number of leucocytes in the peripheral and in the central circulation was practically the same, varying only within the limit of error, or slightly over, sometimes one way sometimes the other.

3. Following the administration of nuclein solution there was immediately, that is by the end of five or ten minutes, a noticeable increase in the number of leucocytes *in both the central and peripheral circulation.*

4. At this time the percentage increase was most marked in the young mononuclear forms, which in some instances rose as high as 60 per cent. of the whole within fifteen minutes, while at the same time the proportion of polymorphonuclear elements was proportionately low.

5. The longer after the injection of nuclein the greater was the actual increase and the number seemed to steadily rise *in both the peripheral and central circulation.*

As the title of this paper indicates, it is but a preliminary study, and we recognize the fact that there are a large number of questions, upon which we have not attempted to touch, that are of the greatest interest and importance. One of these questions relates to the condition of the blood a day or two after the injection of nuclein. We believe, from certain facts that we have already stated, and from other observations that we have made, that we will find a gradual increase in the proportion of polymorphonuclear elements beginning an hour or so after the injection and gradually increasing, and that as this rises there will be a falling off in the proportion of mononuclear forms as they gradually mature. Work on this point will be begun in the near future, as well as on some others that have suggested themselves to us.

The following tables taken from our record book give the figures in some of our experiments and the percentages calculated from them. It is from these figures that the conclusions just stated were drawn. A comparison of the following tables shows that the increase in the number of leucocytes begins within a very short time after the injection and steadily rises, and that the greatest percentage increase is in the small mononuclear elements.

Table 1.—Count of the leucocytes in the *peripheral* circulation of a dog before the administration of nuclein and without ether:

Varieties.	Per-centages.	Average total No. of leucocytes per c.mm.
Small mononuclears . . .	10.87	9,200
Large mononuclears . . .	26.07	
Polymorphonuclears . . .	63.06	

Table 2.—Count of the leucocytes in the *peripheral* circulation of a dog under ether and five minutes after an injection of 45 minims of nuclein solution:

Varieties.	Per-centages.	Average total No. of leucocytes per c.mm.
Small mononuclears . . .	42.30	15,600
Large mononuclears . . .	12.82	
Polymorphonuclears . . .	44.87	

Table 3.—Count of the leucocytes in the *peripheral* circulation of a dog under ether and twenty-nine minutes after an injection of 45 minims of nuclein solution:

Varieties.	Per-centages.	Average total No. of leucocytes per c.mm.
Small mononuclears . . .	39.23	20,400
Large mononuclears . . .	18.62	
Polymorphonuclears . . .	40.18	
Eosinophiles.	1.96	

A comparison of the following tables with the foregoing will show that the increase in the number of leucocytes occurred in the central circulation as well as in the peripheral and was not therefore an "affair of distribution."

Table 4.—Count of the leucocytes in the *central* circulation of a dog under ether and before the administration of nuclein solution:

Varieties.	Per-centages.	Average total No. of leucocytes per c.mm.
Small mononuclears . .	15.58	15,400
Large mononuclears . . .	18.18	
Polymorphonuclears . . .	66.23	

Table 5.—Count of the leucocytes in the *central* circulation of a dog under ether and five minutes after an injection of 45 minims of nuclein solution:

Varieties.	Per-centages.	Average total No. of leucocytes per c mm.
Small mononuclears . . .	34.79	18,400
Large mononuclears . . .	19.56	
Polymorphonuclears . . .	44.56	
Eosinophiles.	1.08	

Table 6.—Count of the leucocytes in the *central* circulation of a dog under ether and thirty-five minutes after an injection of 45 minims of nuclein solution:

Varieties.	Per-centages.	Average total No. of leucocytes per c.mm.
Small mononuclears . . .	50.90	22,000
Large mononuclears . . .	14.54	
Polymorphonuclears . . .	33.64	
Eosinophiles.	.91	

By comparing Table 1 with Table 4 and Table 7, which follows, it will be seen that the effect of ether alone is to cause an increase in the total number of leucocytes. There was no count made of the central circulation before the administration of ether, as we did not care to subject the animal to the pain of the operation. The evidence is very clear, however, that there is the same increase in the number of corpuscles in that portion of the vascular system following the anesthetic as there is in the peripheral portion.

Table 7.—Count of the leucocytes in the *peripheral* circulation of a dog after the administration of ether and before the injection of nuclein solution:

Varieties.	Per-centages.	Average total No. of leucocytes per c.mm.
Small mononuclears . . .	8.82	13,600
Large mononuclears . . .	20.50	
Polymorphonuclears . . .	67.64	
Eosinophiles.	2.94	

The figures given in all the preceding tables are taken from the same experiment. This was only one of a large number and each showed practically the same changes, the figures varying, the increase in the number of leucocytes being greater in some and less in others. The number of white corpuscles varies normally in different dogs and each one has its individual ability to react to the stimulation of the nuclein injected, this reaction however being present in every animal experimented with.

NUCLEIN SOLUTION; A CLINICAL STUDY.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY OSCAR R. TOMLINSON, M.D.
NEW YORK INFANT ASYLUM, MOUNT VERNON, N. Y.

In the medical service of an institution like the New York Infant Asylum, where a large number of infants and young children are to be cared for, many of whom are received in a very poor condition of health and with a tendency to various hereditary diseases, it is often difficult to know just how to properly treat many of the more or less chronic ailments they are apt to be afflicted with, and I have endeavored to ascertain if some one of the newer remedies would not be of benefit in those cases we used to call "scrofula," and in fact all of the cases in which we meet with enlarged lymphatic glands, and with persistent discharges from the nose and ears, sore gums, skin eruptions, etc. My attention was attracted a few onths ago to the nuclein solution originated by essor Vaughan of Ann Arbor, and I thought perps it would be of benefit in the class of cases above tioned if it should really prove that the administration of the solution promoted leucocytosis, for if it should do this and if the leucocytes are, as they are theoretically supposed to be, the scavengers of the blood, should we not reasonably expect a beneficial effect from its administration in such cases? I have used the improved nuclein solution 5 per cent. per orem, and the results have been so entirely satisfactory that I will continue its use.

To be quite sure that the nuclein solution does promote leucocytosis, I made careful counts of the leucocytes in four cases, which will be described in detail further on. It will be noted, in referring to the table below, that in three of the four cases, there was a satisfactory notable increase of weight during the administration of the nuclein solution. It will also be noted that in Case 1 the number of leucocytes decreased between April 9 and 24, due I think to the insufficient dose of nuclein which was probably not enough to make any real impression on the blood condition and the advance of the disease. From April 9 to 24 in this case I gave only ½ dram three times a day. On the twenty-fourth I increased the dose to 1 dram, and on May 1 to 1½ drams, and found on May 5 that the number of leucocytes per c.mm. had gone up from 6,000 to 22,000. I am, however, at a loss to account for the decrease in the number of leucocytes during the latter part of the treatment of Cases 2 and 4, but whatever may be the cause of this the cases improved very rapidly and in a satisfactory manner. It will be noted from the table that the administration of nuclein solution caused an increase in temperature in all cases. Quite early in my experiments with this preparation I reached the conclusion that until a sufficient dose was given to produce some elevation of temperature, I would not expect any very rapid improvement.

Another thing which attracted my attention was the evidently stimulating properties of nuclein solution, for when I gave it to Case 5 the child was suffering from a suppurating abscess; the amount of the discharge was markedly increased, so much so that I felt somewhat doubtful about the advisability of continuing the treatment, but did so and the results were entirely satisfactory as will be noticed from referring to the record of this case. This effect of temporarily aggravating the suppuration is a very interesting fact and well worth careful consideration, but it should not discourage us from using the remedy, for it has convinced me of the strikingly stimulating effect of nuclein and I might say, aggressive qualities of the leucocytes in endeavoring to rid the body of detrimental germs. In a case of "scrofula," if administered before suppuration commences I feel sure it will prevent it, but after suppuration has actually taken place it will increase it, but at the same time make the final cure all the more complete. I will first report the four cases in which I kept a record of weights, temperatures, increase in dose and the blood-counting.

Case 1.—O. B. Mucopurulent discharge from nose and ears. Gums and the mucous membrane of the mouth in an unhealthy condition and bleed for the slightest irritation. Chronic conjunctivitis. Very irritable. Large head. Protruding abdomen. All of the usual symptoms of rachitis. Began to administer the nuclein solution April 9; ½ dram three times a day before feeding. Temperature normal or not above 99 degrees until May 1, when I increased the dose to 1½ drams. (I began to give 1 dram on April 24, which made little impression.) It will be noted from the table that on May 5 the weight had increased to fifteen pounds and the temperature was averaging 100 degrees, while the number of leucocytes increased from 6,000 to 22,000 per c.mm. In this case it appeared that the temperature would not begin to go up until some days after the dose was increased, that it would stay up for a couple of days and then decrease again. The child began to improve in apppearance by May 5 and on May 19 was well and all of the disagreeable symptoms and complications had disappeared.

Case 2—W. H., a weak, pale and fretful infant, extremely nervous and irritable. Enlarged lymphatic glands, large head and protruding abdomen. Discharge from nose and ears. Began treatment April 9 and it is being continued at this writing (May 22). The case has improved very much in every respect, all discharges have stopped, the formerly enlarged glands are no longer noticeable and I confidently expect a complete restoration to health in a short time.

Case 3.—A. L. Phlegmatic temperament. About same condition as Case 2. Enlarged glands, decayed teeth, discharge from nostrils. All disagreeable symptoms almost entirely disappeared at this time.

Case 4.—C. M. Discharge from nose and ears; enlarged glands, nervous temperament, condition very similar to that of Case 1. This case is now well and the treatment discontinued.

Date.	Dose.	Weight.	Temperature.	Leucocytes.
O. B., male; age, 1 year and 4 months				
April 9	½ʒ	13 lb. 10 oz.	99 to 100 ° F.	9,000 per c.m.
April 24	1 ʒ	13 lb. 13 oz.	99 to 100 ° F.	6,000 per c.m.

May 5	2 ʒ	17 lb. 7 oz.		32,000 per c.m.
May 19.	2 ʒ	18 lb. 3 oz.		16,000 per c.m.

I will also report five cases in which the results of the treatment were just as satisfactory but in which I did not take time to make blood counts, as I thought the four cases above given would be sufficient to illustrate the increase of leucocytes due to the admistration of nuclein solution.

Case 5.—E. K., female, aged 3 years. Had bronchopneumonia which was followed by whooping cough; then chronic bronchitis; then there was another attack of bronchopneumonia followed by a foul smelling discharge from the right nostril and right ear. Bleeding gums, restless and irritable. I began the treatment by administering ½ dram of nuclein but soon increased the dose to 1½ drams, which produced only a slight rise in temperature, but the child improved rapidly. For a week after the treatment was begun the discharge from the ear and nostril was largely increased in quantity and the odor of the discharge also appeared to be increased. After the first week the discharge gradually diminished, first in odor and then in quantity. The child became bright and playful and finally the nostril healed and there had been so much loss of tissue that the healing process almost closed the opening. The ear healed also. The lung symptoms disappeared and within five weeks from the beginning of the nuclein treatment the child was apparently perfectly well.

Case 6—N. R., female, aged 2 years and 6 months, listless, emaciated, chronic eczema with boils in various parts of the body. Discharge from left ear. Nuclein, 1 dram, was given three times a day and all of the symptoms, including the eczema disappeared and the child became energetic and playful. I do not attempt to account for the relief of the eczema from the administration of the nuclein, but it certainly disappeared with the other complications after only three weeks' treatment.

Case 7.—A. K , female, aged 10 months. The submaxillary glands were swollen, were large and sensitive to the touch, and it appeared as if they were on the verge of suppuration, but within a few days after the nuclein treatment was begun the glands began to subside and after four weeks' treatment the child was entirely well.

Case 8.—L. H., female, aged 1 year. A typical case of "scrofula." One of the glands was already suppurating when I began the treatment. Immediately after two more glands broke down and there were large quantities of pus thrown off. The suppurative process appeared to be hastened for a time, but within six weeks from the beginning of treatment there was no evidence of the disease remaining.

Case 9.—A. H., female, aged 8 months. Another case of "scrofula." Two glands were discharging. Soon after the administration of nuclein was begun the discharge disappeared and after three weeks' treatment the patient was discharged cured.

I fully appreciate the difficulties involved in the treatment of cases of this character with nuclein solution, but I feel that I can urge upon the profession the importance of the remedy and that it is worth while in the chronic ailments of children of the character described to undertake the treatment, but being careful to caution the parents or guardian of the child that the treatment must be carried on systematically and for some weeks and that the case must be examined from time to time and the dose carefully increased if necessary, and its temperature and weight noted, even if it is not convenient to have a blood count made. Nuclein solution can not be used successfully if it is prescribed offhand and the parents allowed to regulate the treatment without reference to the conditions above named. I am also fully convinced that most clinicians who have prescribed this nuclein solution have given it in too small a dose. I found that even young infants could take, with advantage, as much as two teaspoonsful three times a day, and if a less dose had been given the treatment would not have been successful. I found that young children take the nuclein solution more readily if the the proper dose is mixed with a little sweetened water.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

MILITARY SURGERY UNDER FREDERICK THE GREAT.

(*Continued from page 438.*)

The third in the group was *John Christian Anton Theden* (1714–1797), whose name was often distorted by his contemporaries into Theede, Theeden or Thede. He was born in the Mecklenburg village of Steinbeck, where his father was a farmer, being the eleventh of twenty-three children, as his son-in-law, Mayer, the professor of anatomy, relates. Well versed in arithmetic and writing, he went out to service in his thirteenth year as servant and scribe, but after four years gave up this insufferable occupation to learn the tailor's trade with his brother. But this did not please him either; surgery was next in order. When he had spent three years in a barber shop without learning anything properly, he felt his ambition stimulated by the character of Odysseus, with which he became acquainted through a translation of Homer; he went in 1734 into service in Rostock, and with other barber journeymen listened to an anatomic colleague on "Heister's Manual." His travels led him to Hamburg, Lübeck and Danzig, from which place, in 1737, he entered the Buddenbrok cuirassier regiment as squadron surgeon. Active day and night, he soon won for himself the love of his superiors. As his regimental surgeon, Heise himself, prepared the medicines and had the herbs gathered for that purpose, Theden was often employed in the laboratory, and soon gained a readiness in pharmaceutic work. In a review, King Frederick William desired to make him a salaried surgeon in Berlin, which Heise wished to prevent. In 1740 Theden was ordered to the hospital of Strehlen, where he became acquainted with Schaarschmidt, Holtzendorff and Boness. There he caught the spotted fever and was taken to Breslau, from which place he went, after his recovery, to the Bohemian winter quarters. In 1741, he attended the wounded after the battle of Czaslau, and made the acquaintance of the physicians there, Drs. Siegmund Hahn, father and son, who made an extensive use of cold water and ice in external and internal diseases. Theden learned from them the application of cold water in dangerous inflammations. He was sent to take charge of 7,000 wounded Austrians in the hospital at Striegau, where he contracted dysentery. He then attached himself as battalion surgeon to the Holstein regiment, but soon left it on account of the great danger of his being impressed into the military service, and upon the recommendation of the regimental surgeon traveled as quickly as possible to Berlin. There, in the next two years, he began a regular course of study under the direction of Schaarschmidt, who interested himself in his behalf. He became a salaried surgeon and soon gained the friendship of Schmucker, who gave him admission to his house and to his operations. Theden worked industriously at anatomy, and prepared specimens so beautifully that Vogel in Göttingen gave him 50 thalers for some ophthalmic specimens. In 1748 he entered the Treskow infantry regiment in Stettin as regimental surgeon. During the Seven Years' War he took part in the battles of Prague, Leuthen, Hochkirch and others, and directed various hospitals. King Frederick II. became acquainted with him while he was treating General von Geist, whose upper arm had been shattered; the general died and bequeathed 1,000 thalers to Theden. At the suggestion of Cothenius he was appointed third surgeon-general in 1758. A consultation is said to have called him from Berlin to Schwedt, on account of the injured foot of Duke Eugene of Würtemberg. He climbed into the carriage with the duke's courier, but they had gone scarcely a mile from Berlin when the drunken postilion tipped the carriage over and Theden's left upper arm was broken. Henckel cured him within six weeks by the application of his arquebusade-water. At the end of the war he returned to Berlin and in 1767 became surgeon of the entire artillery corps. The last Silesian war took him again to the field, whereupon he became first surgeon-general in 1786, after Schmucker's death, and when he himself was an old man; he was also made a member of the chief medical college. In the following year "Father Theden," who had served three kings of Prussia, celebrated his fifty year jubilee. The celebration with addresses, memorial medals, banquets and balls lasted three days; in addition the medical faculty in Frankfort bestowed upon him the doctor's degree. One year after Bilguer's death Theden also went to his eternal rest, after sixty years of service as general staff surgeon.

In his youth he was a religious enthusiast. Even in his later years he expressed regret for his careless rly education which left his "heart for a long time llous," and felt, as he frankly confessed, a tendency toward envy which during his life cost him the greatest pains to repress. What was the cause of this envy and of his bad temper? Let us hear and wonder; Theden supposed that in the act of procreation the soul of his father had been ruled by those emotions. This drove him from Hamburg, because his religious principles were not strong enough to withstand the temptations of that city. As a squadron surgeon he took instructions from the Pietists, and soon entered the order of Free Masons. When he was taken with spotted fever he desired to take the sacrament and was so tormented by conscientious scruples that he begged a Magister to convince him of the existence of God. If one considers that Theden had very little general culture, but made a very creditable record for himself, it may perhaps explain his self-complacency and the frequent obtrusion of the first person, which gives his writing an unpleasant flavor. The following are samples of this: "I write not from mercenary motives . . . am too proud to pass as a mere copier . . . do not desire to become famous and am satisfied if I can only be useful . . . am sympathetic by nature, and therefore avoid all operations so long as there is any other remedy at hand . . . am above self-love, thank heaven! and have just as little tendency to boast as to maliciously censure and defame other men. . . ." A quarrel, which his son-in-law Mayer had with his colleague Walter, moved Theden to write to the latter two letters, which Walter's son purposely published with all their orthographic mistakes. He says in them: "I consider myself a suffering Christian, and should it not be possible for you to withdraw this unhappy hatred against me, then I shall even be patient in the issue, for my days are passing, and I should consider it in the place of others an offense to God, inviting my own damnation, if I in repeating the Lord's Prayer should ask forgiveness as I forgave my debtors" (1779). Later he threatened the aged Walter, saying that he could tell His Majesty many things that would not be agreeable to him. When Theden in his eighty-first year published the third volume of his new "Observations," he took "leave for the last time of his dear friends and of his enemies, nevertheless dear to him. The applause and love of the former have made the best part of the happiness of my life. I have only two or three enemies. I will soon go before God in perfect peace, and to all my enemies I extend the wish that they may pass to eternity in due time just as peacefully." Theden was greatly afflicted with illness; besides that already mentioned he suffered in consequence of excessive tobacco smoking and tea drinking (for instance, in Hamburg he was accustomed, morning and afternoon, to drink over two pounds of the "cursed tea-water" with milk, for thirty-two years, with nausea, continual vertigo and severe hypochondria, insomuch that in his youth he often thought he would throw himself into the river. Instead of taking such a cold bath, he resolved to take water in great quantities internally, and was afterward very well. His continuous good health during his last forty years, excepting for a cracking of the skin from which he suffered for ten years, and which he believed he owed to the daily drinking of five to seven quarts of cold water, thereby taking up the lance in favor of the water-doctors, who were at that time bitterly reviled.

Among Theden's innovations his arquebusade-water made a sensation. As Schmucker had kept his eye-wash secret, Theden did likewise with his remedy: "I had sufficient reasons for not divulging this at once." In 1782 the world received notice of an improvement in this remedy, by which, instead of the so-called sorrel-water, vinegar was used in the arquebusade. For the tincture of antimony he used a new preparation which made him an expense of several hundred thalers, as he himself usually prepared most of the medicines which he used as surgeon-general, in order to have them as good as possible. When the Sardinian ambassador to Berlin, the Marquis von Rosignan, had shown him India-rubber, which de la Condamine first described minutely to the Paris academy in 1751, Theden undertook to make surgical instruments from the solvent resina elastica (in naphtha vitrioli or sulphuric acid according to Macquer), which was then very expensive. He made elastic catheters principally, which he in 1777 introduced to A. G. Richter, afterward his friend, by means of a circular, and sold for six thalers apiece, or four for three Louis d'or. He also made breast-pumps out of India-rubber which were very similar to those at present made of shell, upon which a funnel-shaped sucking-bottle was placed which drew out the nipple. In later years he lacked the time to make the instruments himself. Among his other improvements should be especially mentioned a method named for him of enveloping the limbs from the fingers and toes upward for the resorption of exhausted fluids, particularly after unsuccessful bleeding and the aneurysma spurium arising therefrom in old sores, dropsies, varices, contusions, and also for the alleviation of pain in certain operations, as in the opening of a felon. Theden made himself further known through his concave splints of walnut for fractures, his polyp-tweezers and the operation of hydrocele; he declaimed against the great number of complicated and superfluous instruments, and he expressed of Heister the wish that he had used his influence for the reform of useless instruments. He made a mistake in defending so earnestly the tamponade of the arteries instead of the ligature. The field-hospitals owed to him many improvements, especially the introduction of his system of ventilation, which has already been described in chapter four.

At an advanced age after having joined in every campaign for thirty-four years, Theden began to write. He began in 1771 with the first part of his "New Notes and Experiences for the Enrichment of Surgical Science," but acknowledged later, just as Schmucker had done, that on account of pressing duties which only permitted him to write at night, this book was too hastily prepared and not sufficiently elucidated. "While I was never a writer and usually feared to allow the few things of mine to appear, . . . nevertheless this book brought me more honor than I myself could hope for, in proportion to my experience, scientific education and culture." In this volume are chapters on the envelopment of the extremities, arquebusade-water, tamponade of the arteries, douche for ankylosis, gunshot wounds, cold applications in strangulated hernia, superfluous instruments, among which in most cases Theden counted scissors, which were said to cause a bruised wound and therefore more inflammation and pain than the bistoury, etc. The second volume appeared in 1782 and contained articles on hyrdocele, trepanation, exfoliation of the bones, aneurysms, concussions, tincture of antimony, various fractures, etc. In the third volume (1795) were essays on sublimate, intermittent fever, wounds of the joints, the opening of the bladder, the results of drinking cold water, electricity, castration, treatment of gunshot wounds, etc. In this he published for the first time the decoction for syphilis given him by the Saxon general-staff physician Zittmann (†1757). In 1774 the "Instructions for under-surgeons in the army" already mentioned appeared.

The other Prussian military physicians were of less importance than these three surgeon-generals. *Voitus* (1745–1787), the son of a schoolmaster, had through zealous diligence raised himself from poverty. At the close of the Seven Years' War he went to Berlin as company surgeon, where he shared with some poor artisans a little room which scarcely allowed him to stand upright, and subsisted almost entirely on herrings and potatoes. Schmucker accepted him as a pensioner, then promoted him to regimental surgeon. Frederick II. sent him to France in order to learn new operations, especially that of the rectal fistula. In Paris he also studied obstetrics. In 1779, after Henckel's death, he became professor of surgery in the Colleg. Med. Chir., chief surgeon in the Charité, and later third surgeon-general. Except two addresses on the acquirements and qualifications of a good surgeon, he published nothing, but was a popular teacher and obstetrician. His successor as professor, surgeon in the Charité and surgeon-general was *Mursinna* (1744–1823). The son of a cloth-maker, and at first destined for that trade, he entered a barber shop in his 13th year and served in Prussian and Russian field-hospitals till Theden made him hospital surgeon. When he saw the institutions of Berlin he vowed "not to rest until he himself became a professor." After peace was restored the want of money drove him again to the barber shop until he was made a company surgeon, and in 1887 was promoted to be third surgeon-general. When he had taken part in the war from 1790 to 1807, but was mustered out at the disbanding of the army, he devoted himself to the profession of teaching, having previously been appointed first professor of surgery in the Collegium Medico-Chirurgicum, and chief surgeon and first obstetrician in the Charité. In his "Medico-Chirurgical Observations," (2 Vols. 1782; "New Observations" 1796), which followed works on dysentery and obstetrics, one meets things which allow Mursinna's veracity to appear somewhat questionable. For example, he asserts, among other things, that within forty years he performed 908 extractions of cataract. *Gorcke* (1750-1822) was a man of pre-eminent administrative ability; he likewise began as a company surgeon and became, after Theden's death, general-staff physician and chief of the military medical department of Prussia. Extensive travels had made him familiar with the medical writings, hospital management and educational institutions at home and abroad, the advantages of which he sought to bestow upon his fatherland. During the Rhine campaign he introduced movable field-hospitals, improved the service in them and founded the Pépinière. Upon his suggestion in 1795 were first introduced into the Prussian hospitals, ambulances which rested upon springs, after he had bought such a one in Rinteln, which the English army had left behind them on their departure from Holland, at a cost of 250 thalers apiece. Twelve such wagons were built at Potsdam after this pattern (each of which would carry six severely wounded men lying down and a number of slightly wounded who could sit up). In the year 1806 he had the hospitals under his direction, gave the company surgeons an increase of salary, appointed general physicians to the army-corps, founded a medical staff and secured a definite military rank for military physicians. It was also due to him that the first physician of a field-hospital became at the same time director of it. Upon his recommendation in the year 1811, a medico-surgical academy for the army was erected in place of the Collegium Medico-Chirurgicum abolished in 1809 at the founding of the Berlin University. *One of his chief services was* to have the system of the distribution of patients formulated and established. These various improvements were tested during the war for freedom, where chiefly his name and his personality served the necessary medical force. He was the regenerator of the Prussian sanitary system of the army.

Among the other regimental surgeons there were a few who were urged by Bilguer and Schmucker to literary work, although as a rule nothing more than a simple record of cases without any scientific value was produced from that source. Bilguer's "Surgical Observations". and Schmucker's "Miscellaneous Essays," as well as the periodicals of Loder, Hufeland, Mursinna and Arnemann comprised these productions. One of the most talented of the regimental surgeons was *Jasser*, whose name is remembered in our own time through a sulphur salve for scabies. To be sure he was not the originator of this, for as early as the year 1667 a Prussian court physician Balthasar Timaeus à Guldenklee ("Cas. Med." Leipsic, p. 277) had used such a salve for scabies; but it had been forgotten. Jasser received the ointment in 1778 during the war from his landlady whose dead husband had cured many soldiers with it, and he treated 260 cases of scabies with it; Schmucker and Theden followed his method. Besides this he was the first in Germany to perform a trepanation of the pr. mastoideus, and he published an account of the treatment of a liver wound, in which he had successfully bound up a piece fallen forward and strangulated; likewise an injury of the larynx and esophagus. His colleague *Ollenroth* described a successful tapping of the breast with inhalations of warm vapor, a pericardial wound and a second lithotomy upon the same patient; he also invented out of sixty-one smooth tin balls and a sponge an instrument still in existence, for extracting foreign bodies from the esophagus. He recommended the mixture of cold water and milk in nephritis, cold application in strangulated hernia, etc. *Seeliger* recounts the healing of a shattered arm which hung by only a small strip containing the nerves and arteries. *Jung* cured a hand cut almost entirely in twain. *Morgenstern* published an account of a case of inflammation of the arm with thrombosis of the arteries. *Rudiger* told of a luxation of the spinal column and a gunshot injury of the neck. *Buddeus* wrote of the uses of amputation in exhaustion. *Horn* recommended cold applications in wounds of the joints, and objected strenuously to the bleeding of exhausted soldiers. *Cramer* cured an aneurysm by compression, while he laid a long compress upon the course of the arteries and enveloped the entire arm. These observations are all in Schmucker's "Miscellaneous Essays." The medico-surgical writings of *Hemmann* are said to have been declared fabrications by the author upon his death bed.

The medical writers in the army were extraordinarily rare, because too few educated physicians were in the field; therefore very little is known of the diseases in the Seven Years' War. *Baldinger* was a noted exception, who had taken part in this war and wrote on the "Diseases of an Army" (1765). He was later professor of medicine in Jena, Göttingen and Marburg. More of a scholar than practitioner was Professor *Ackermann* in Altdorf, who published a "Manual of the Medical Science of War" (2 Vols. 1795), and another on "Medical and Surgical Science in Armies" (2 Vols. 1797).

We now turn to *Austria* and at first find there the same crude conditions as those in Prussia. There, also, the under-physicians were wholly ignorant. Escaped from the barber shop they knew nothing of surgery, nothing of internal medicine, and could do scarcely more than nurses. One may glance at the primitive directions which van Swieten, who indeed had never been in the field, soon after the beginning of the Seven Years' War, laid down in a manual on "The Treatment of Diseases Prevalent in the Army," in order to gain an idea of the low plane of education of the military physicians. In this work is explained the absurdity in Austria (just as in Prussia) of the bleeding, without discrimination, of wearied soldiers upon the march. This custom was so general that even the officers in the spring and fall ordered bleeding and purgatives for the whole company. Thus more soldiers perished by the lancet than by the lance! Naturally, no good surgeon would serve in Austria for a monthly salary of from six to ten guilders. Indeed, they forbade the boxing of ears in the army, cashiered every officer and reduced the under-officers, and sentenced them to run the gauntlet six times through three hundred men, if they kicked a soldier or struck him. But about the same time (1769) they gave the staff-officer the right to address the regimental surgeon as "*Er*," and in the review, when everyone was allotted his rank, placed him behind the last cadet. For the want of good surgeons Maria Theresa had French surgeons brought, but they were for the most part unskilled, ignorant of the language and customs of the country, and did more harm than good in the army. The religious intolerance brought it about that all the protestant field physicians were taken out of the army, in the beginning of the Seven Years' War, if they would not be converted. Joseph II. had first to convince himself of the misery of the wounded soldiers and the small number of capable surgeons, in order to institute a thorough-going reform by the founding of Joseph's Academy. He said at the end of his life, that "whatever could be devised for the cure of sick and wounded men, or for their relief and maintenance, had never been neglected by him, and every man had been precious to him." He gave his staff and regimental surgeons, who had to be doctors, permission to treat civilians externally and internally, and he gave the under-surgeons the rights of their burgher colleagues; he increased the salaries in order to immediately abolish the abuse of the field surgeons accepting presents for visiting the recruits, and he pensioned the widows of field surgeons.

When Prussia in 1787 came forward with a new regulation, the Austrian emperor within a year thereafter had the sanitary system of the army reorganized by Brambilla. First of all, the Austrian military physician was to present himself in his uniform. At first he wore that of the regiment in which he served; in that way many annoyances arose, so that they devised a special dress. The coat was white and dark blue mixed, lined with red sleeves faced with black velvet, the waistcoat and breeches of red cloth. At each side of his face hung a single curl; behind, the hair was plaited with a black ribbon. Buttons, sword, and tassel on the black hat were gilded; the amount of gold increased with the rank until the surgeon-general was quite overloaded with it. This so-called proto-surgeon, at the same time court counsellor and court surgeon to the Emperor, director of Joseph's Academy, and inspector-general of all the military hospitals, was war counsellor *only at the court*; in the field, however, he was subordinate to the commanding general of the army. Under him were the professors of the Academy, then successively, the staff, regimental, battalion and under-surgeon, which last had the rank of a sergeant. While on the one hand Joseph II. sought to elevate their station, and commanded the regimental surgeons to address their subordinates as "*Sie*, because they were scientific men," he forbade them to write complimentary letters to their superiors at New Years and other festivals, yet on the other hand restricted them. For example, *no one could publish a scientific work without having* first submitted it to the proto-surgeon and received his permission. It is asserted that in the nineties, the Austrian field-physicians were threatened with arrest if they did not treat the patients according to the Brown system. Their salaries were as follows:

	In Peace.	In War.
Proto surgeon . . .	3,000 guilders.	Besides the salary, rations for six horses and four bread rations with the field quota.
Staff-surgeon . . .	600 guilders and free quarters.	1,200 guilders, rations for four horses and four bread rations.
Regimental surgeon	600 guilders.	. . . .
Battalion surgeon . .	240 guilders.	. . . .
Under-surgeon .	168 guilders and quarters.	180 guilders.

The pensions for staff-surgeons amounted to 400 guilders; for battalion surgeons 100 guilders; if a regimental surgeon wished to marry he must give security to the amount of 1500 guilders. When vacancies occurred the commander had the right to make suggestions to the proto-surgeon. While the soldiers were treated gratuitously, the higher officers had to pay if they became sick through debauchery and intemperate living.

On the breaking out of war the proto-surgeon appointed the staff-surgeons to the army and to the hospitals; he himself remained with the main army, together with two commanding staff-surgeons for the the right and left wings. Each company received its under-surgeons. The army corps were provided with instruments and medicine chests out of the magazine in Joseph's Academy. Each regiment received two chests, which were packed upon mules or horses; they also received sufficient bandaging material and instruments, which were carried in the knapsacks. During a battle the proto-surgeon was stationed in the rear with the staff-surgeons, where a flag indicated the place for bandaging. The transient hospitals were located in the adjacent villages. All the military physicians were expressly ordered to "care for the wounded officers first and then for the other men, friend or foe, with the same zeal." The shattered limbs were placed in splints, or if these were lacking, they were wrapped with the shirts of the wounded. The staff-surgeon was to take care that limbs were not amputated unnecessarily. It appeared to be the custom, especially among the Austrians, when wounded, to wish for an amputation of their limbs in order to obtain a pension. Accordingly, in the hospital at Streigau, in 1745, Theden was obliged to make an extraordinarily large number of amputations at the solicitation of the imprisoned Austrian generals. Those who were severely wounded were transported to the chief hospital in wagons, with a physician accompanying them. For this purpose churches, castles, large buildings or barracks were appropriated. The wounded among our own men were separated from those of the enemy, and those needing medical treatment from those needing surgical attendance. The chief hospital was under the supervision of staff-surgeons, of whom each one looked after four hundred patients, bandaged the worst cases twice a day with his own hands, performed the important operations and reported every two months to the proto-surgeon. From 100 to 150 sick or wounded were allotted to each over-surgeon with four under-surgeons; but these were changed every one or two months from the inner to the outer stations. If they did not behave themselves the staff-surgeon had the right to put them under arrest for a few days. Soldiers, for the most part those who were awkward in drill or very disagreeable to their comrades, served as attendants. Under strict diet the food was divided into one-fourth, one-half, three-fourths and full portions. The strict diet consisted of a meat soup, sometimes made stronger by the yolk of an egg, and was given several times a day, and also at night to the severe cases. A full portion for a convalescent consisted of soup, five ounces of boiled beef without bones, vegetables, bread, and a pint of wine or beer. Experience in the Seven Years' War had taught that in consequence of the narrow quarters and bad ventilation, typhoid fever and scurvy wrought almost as great havoc in the royal army as did the bullets of the enemy. They insisted strenuously therefore on fresh air in the hospitals, and even went to the extreme of having three air-passages in the wards; an upper one for the fresh air, a middle and lower one to carry off the foul air. The beds, of which each patient had his own, were provided with a black tablet and number, and placed far enough apart that a table would fit between them. Instead of a chimney, openings were made in the windows, and Theden's ventilators were used in the wards, while fumigation was discountenanced. In summer, in good weather, the doors and windows remained open the whole day; in winter they were closed, but fresh air was admitted through the ventilators, morning and evening, after the bandaging had been done. Tobacco smoking in the wards was strictly forbidden.

Among the Austrian military physicians scarcely one deserves to be mentioned. Aside from Brambilla and a few professors in Joseph's Academy, who have already been mentioned, there is left to introduce only the field staff-physician Louvrier, who with Mursinna wrote a prize essay of that academy on "The Indications of Trepanning" (1800) and re-introduced the inunction cure for syphilis.

There is little to relate of the rest of Germany. Scientific aspirations were felt in Hanover earlier than in other states, for there King George I. of England, for the sake of advancing surgery, provided a course of instruction for his German troops. It was conducted by the court field-physician Wolf, court and general-staff surgeon J. E. Wreden, and general hospital surgeon Kannengiesser, and served to unite the Hanoverian regimental surgeons, of whom some had studied anatomy and surgery in Paris at the expense of the state; it also moved them in 1721 to undertake a yearly publication of their most important observations. *Wreden* published this collection in 1722-23, as "Collect. chir." *Evers* later came to the front among the Hanoverians; he had studied in Berlin and after the Seven Years' War had lived in Paris and Rouen, where he had dwelled with le Cat several months in order to learn lithotomy. He devised a bandage for the cure of the severed extensors of the finger and also for the transverse fracture of the patella, and described a cure of fistula of the anus without operation. (Neue vollst. Bemerk. und Erfahr. 1787; and several papers in Richter's Bibliothek.) It has already been mentioned that a Collegium Med. Chir. for the better training of army surgeons in *Saxony* was erected in Dresden under Pitschel (1748). In *Wurtemberg*, Duke Charles added a medical faculty to his military academy (Carlsschule) when he removed it to Stuttgart in 1775. Among the seven students who first reported to that school was Schiller. Toilets were made, dinner eaten, prayers said, lectures heard, and retiring at night, all were done by order. At dinner the students filed off in two columns, the nobles to the right and the commoners to the left, into the dining room. They fronted about to the table and upon a signal all folded their hands in prayer. That nothing could be accomplished by this drumstick discipline needs no demonstration. *Bavaria,* in the year 1802, first inaugerated a reform in its army sanitation, and from that time on no one was promoted to regimental surgeon who had not graduated from the gymnasium and studied the whole of surgery so as to combine in himself physician and surgeon.

SOCIETY PROCEEDINGS.

American Association of Obstetricians and Gynecologists.

Proceedings of the Tenth Annual Meeting, held at Niagara Falls, N. Y., Aug. 17-20, 1897.

(*Concluded from page 441.*)

SECOND DAY—MORNING SESSION.

POST-CLIMACTERIC CONDITIONS THAT SIMULATE ADVANCED UTERINE CANCER.

A paper on this subject was read by Dr. M. ROSENWASSER of Cleveland, Ohio. The writer commends the teaching that irregular hemorrhages and sero-sanguineous discharges, whether occurring during the parturient stage or long after the menopause, are good and sufficient reasons to suspect malignancy. We carefully watch for early symptoms and by their detection occasionally succeed in removing the disease while it is still local. On the other hand, we sometimes are caught off our guard when confronted by post-climacteric cases presenting all the classic characteristics of advanced malignant disease. Without the same circumspection exercised in the early stages we thoughtlessly pronounce the case beyond remedy or hope, specifying even the extreme possibility of life. The text-books are deficient in not sounding a note of warning against possible errors in the late stages. The so-called classic symptoms may be due to other (not malignant) conditions of the genital tract. Owing to effacement of the vaginal portion of the cervix in old age the differential diagnosis is in most cases limited to corporeal diseases of the uterus. Before the diagnosis of corporeal cancer can be made other diseases must be excluded.

The conditions which are likely to simulate advanced cancer are the following: 1. Senile vaginitis. 2. Foreign bodies in the vagina. 3. Gangrenous fibroids. 4. Atrophic, senile or post-climacteric endometritis. 5. Post climacteric pyometra.

Of these conditions the last is especially liable to lead to errors. The writer gave the details of a case of pyometra occurring recently in his own experience and submitted abstracts of five more or less similar instances found scattered in the literature of the past seven years. In all these cases either a positive or provisional diagnosis of corporeal cancer had been made.

In conclusion, the author called attention to the singular fact that in the presence of the essential conditions—age, low vitality, cicatricial tissue, adhesions, chronic inflammation and irritating discharges—cases of transformation into malignant disease are either unknown or exceedingly rare.

(The afternoon was devoted to sight-seeing.)

EVENING SESSION.

Dr. RICHARD DOUGLAS of Nashville, Tenn., followed with a contribution on

CERTAIN CYSTS OF THE ABDOMINAL WALL,

in which he confined himself to a consideration of abnormalities of the urachus, and reported an interesting case of urachal cyst which occurred in a woman 36 years of age, married eleven years and sterile.

CONSERVATION OF THE OVARY.

A paper on this subject was read by Dr. B. SHERWOOD-DUNN of Los Angeles, Cal. The author said that Brown Sequard believed and taught as a principle of physiology that every gland, whether *or not* provided with excretive ducts, gives to the blood a certain useful principle, the absence of which is felt and made apparent after their extirpation, or the destruction or modification of their functional activity by disease. The recent publication of researches made by Mond and Chrobak of Vienna, Jayle and Lissac of Paris, Mainzer of Berlin and Muret of Lauzanne, had given definite form to certain ideas that the speaker had conceived upon this subject, born of a series of observations taken in his hospital service in Paris of a variety of troubles and functional disturbances which more or less constantly follow as a result of double oöphorectomy. These various troubles and functional derangements, which are constant although variable in degree in women who have had the menopause anticipated by castration, form to his mind one of the strongest arguments in support of the glandular theory.

From observations made upon 100 cases operated upon in Broca and St. Louis Hospitals in Paris he found that where the woman had prematurely lost both ovaries 78 per cent. subsequently suffered a notable loss of memory; 60 per cent. were troubled with flashes of heat and vertigo; 50 per cent. confessed to a change in their character, having become more irritable, less patient, and some of them so changed as to give way to violent and irresponsible fits of temper; 42 per cent. suffered more or less from mental depression and 10 per cent. were so depressed as to verge upon melancholia. In 75 per cent. there was a diminution in sexual desire and some of these claimed they experienced no sexual pleasure; 13 per cent. were not relieved of the pain from which they suffered; 35 per cent. increased in weight and some became abnormally fat. Some complained of a diminution in the power of vision; 12 per cent. noted a change in the tone of their voice to a heavier, more masculine quality. Some 15 per cent. suffered from irregular attacks of minor skin affection; 25 per cent. had severe headaches, as a rule increased in intensity at the menstrual period. Equally as many complained of nightmare, more or less constant, while about 5 per cent. suffered from insomnia. In a few cases there existed a sexual hyperexcitability not present prior to the castration. He particularly noted a few cases presenting gastric reflexes where without any premonitory symptoms or apparent cause the stomach would reject food or refuse to prepare it for intestinal digestion and the consequent distress following the fermentation compelled the patient to seek relief. It should be noted that usually these troubles were more marked in women under 30 or 33 years of age.

He had been favorably disposed to the hypothesis advanced by Brown-Sequard for some time and any skepticism that he may have entertained of the theory of ovarian secretion and its usefulness and necessity to the equipoise of the whole system has been completely dissipated by the results of experiments made with ovarian substance, or ovarin, in patients who have lost both ovaries or were suffering from troubles which in a greater or less measure were due to a diseased condition of the ovary. In the observations of the authorities mentioned use was made of: 1. The ovary in its natural state. 2. The desiccated and powdered organ. 3. Glycerin extract of the ovary. 4. Liquid ovarin. The first form presents two objections, viz., difficulty of obtaining the fresh organ and greater difficulty in getting the patient to take it. The second form of powder has been the one most favored by all and has given as good results as the administration of the hashed fresh ovary or of the glycerin extract or the hypodermic injection of liquid ovarin prepared after the method of Brown-Sequard and preserved in sealed tubes. The essayist has so far used only the powder and the tablets, the latter in only one case, which did not respond as quickly as the others and he soon changed to the powder. But he would not say that one is better than the other as he had not given the tablets a fair trial, neither could he expect such good fortune as that the good effects observed in his three cases will continue in those that follow. The author closed with the report of three interesting cases.

SOME OBSERVATIONS UPON VENTRAL FIXATION.

By Dr. HERMAN E. HAYD of Buffalo.

In this paper it was stated that ventral fixation, or suspension of the uterus, coupled with the various plastic operations upon the cervix and vagina is the only means surgically or anatomically which will fix and support for future comfort and well-being an extremely prolapsed uterus. However, because a uterus sometimes offers a serious impediment to delivery by interfering with the proper dilatation of the organ is no reason why the operation should be relegated to oblivion. *Per contra,* it should be employed to relieve that large class of suffering women who have passed beyond the child-bearing period and who most frequently are the victims of extreme procidentia uteri. In his last six cases of ventral fixation he sewed the uterus to the abdominal wall with chromocized catgut (No. 3) and did not even scarify the peritoneal covering of the uterus. He held the organ by thin sutures, which took in simply the peritoneum and the connective tissue over it; but in one case where the organ was very heavy and the woman short and stout he hitched on to the rectal fascia and muscles. He has invariably sewed the anterior surface of the uterus, feeling more satisfied with the position assumed under these circumstances than where the sutures catch the superior and posterior surface as is advocated in ventral suspension. In the cases he has operated on and those he has examined after operation of ventral suspension he has found the organ in a too anteflected position and it may be the cause of some future annoyance. He has discarded silk and all unabsorbable ligature materials, believing that catgut can be sterilized and rendered absolutely safe and is perfectly manageable.

Dr. James F. W. Ross of Toronto delivered the President's Address. He selected for his subject

SURGERY AND FACTS.

He said the work of the Association was confined between the diaphragm, the perineum and the abdominal walls and that the members had met to cultivate and promote a knowledge of whatever relates to abdominal surgery, obstetrics and gynecology. Attention was drawn to some unsettled questions, the first being peritonitis. Are we able to do more to save the lives of patients suffering from this disease in its acute form than we were ten years ago? Are we not but little better off with all our antiseptic and aseptic washes, gauze and tube drains and purgatives? He was satisfied that surgery could carry us no further when battling with this disease. The question of operating upon the appendix and the diagnosis and treatment of ectopic gestation had been fairly well settled. The method of dealing with the pedicle in ovariotomy had been settled, except for the fact that some operators preferred silk, while others were assured of the safety of catgut. Operations upon the gall bladder and gall ducts had been performed many times during the past ten years and they were now well recognized as proper surgical procedures. The operations of nephrectomy and nephrotomy were looked upon as everyday procedures justified by the consensus of surgical opinion. Abdominal hysterectomy was an operation that had been much improved and simplified, some operators being still wedded to the clamp, while others preferred some of the other methods. The advisability of oöphorectomy for some fibroids could not be doubted. There were two operations performed that Dr. Ross thought are of doubtful value, viz., the fastening of the kidney to the side and the fastening of a uterus anywhere. He considers that 'these operations have been recklessly performed and unnecessarily done.' Another class of operations to which more thought must be given were those for intra abdominal and intrapelvic cancer. When peritoneal cancer has been diagnosticated, surely exploratory operation is uncalled for. Operations for other forms of cancer are of questionable utility. Take, for instance, resection of a cancerous intestine, gastroenterostomy for pyloric cancer and removal of the uterus for uterine cancer. Gastro-enterostomy and resection of the intestine are poor makeshifts. For carcinoma uteri vaginal hysterectomy is the only operation that should be contemplated, but at best it prolongs life for but a short time.

Dr. C. C. Frederick of Buffalo, N. Y., read a paper entitled

WHICH IS THE PREFERABLE OPERATIVE METHOD OF HOLDING THE UTERUS IN POSITION?

'All retroversions do not produce symptoms, but a certain proportion are accompanied by hypertrophy of the uterus, endometritis, leucorrhea, pain, backache, menorrhagia, metrorrhagia or general malaise. Constitutional treatment fails to relieve a large proportion of them without restoration of the uterus to a normal position and a cure of the accompanying hypertrophy and endometritis by reposition. The large factors in the continuance of the ill effect of retroversion are torsion of vessels, infection of the endometrium and defective drainage of the uterine cavity. Retroversion is a first stage of prolapse, and ought for that reason alone to be replaced and held in position. Sterility is one frequent result of retroversion. Results of treatment are good by operation or by holding the uterus in position by a pessary, if possible, together with general tonic treatment, Weir Mitchell rest treatment, etc. A large proportion of cases are cured and eventually get strong and well again. Ventrofixation has been discontinued by the writer in women liable to bear children. He uses it only to hold up the uterus in operation for prolapse and in those cases where he has removed both tubes and desires to hold the uterus in position, time being an element in the operation. The writer has seen no ill results during labor and knows of none occurring in his own cases, although several have borne children. He has seen no recurrence of retroversion, even in those who have borne children. His preference is given to the Alexander operation or some of its modifications in cases of women who have borne children and there are no adhesions or diseases of the adnexa. Women who have never been pregnant are liable to have poorly developed round ligaments, liable to tear away from the anchoring sutures. In these he opens the abdomen and shortens the round ligaments by one of the methods devised by Mann, Dudley or Wylie. He gives Mann's method the preference. Several of the patients have borne children both after the internal and external shortening of the round ligaments, with good results. The writer now uses unabsorbable ligatures or sutures, always using plain catgut or chromicized catgut when a suture is used for a long period. He never has used any of the vaginal methods of fixation, not being pleased with them.

The uterus will now appear as far forward in either of the methods of shortening the round ligaments as it is in normal anteversion, but the pressure upon the posterior surface of the uterus will force the body into extreme anteversion, and in a few months will appear perfectly normal in position.

THIRD DAY—MORNING SESSION.

THE TECHNIQUE OF THE DRY METHOD

was the title of a paper by Dr. Edwin Walker of Evansville, Ind., in which he said that by the dry method is meant a technique in which no water or other fluid is used. This does not apply to the preparation before the operation. After the first stroke of the knife until the wound is closed, not a drop of water is used. The writer has employed it exclusively for several years with good results. The technique is as follows: Nurses are instructed to use every precaution to prevent soiling the hands in septic cases and to thoroughly disinfect the hands after any suspicion of contamination. Every instrument used is sterilized before it is put away. The hands are scrubbed thoroughly with a brush, with liquid soap (equal parts of green soap, glycerin and alcohol), and repeatedly rinsed in sterile water. They are then wiped off with alcohol, dipped for two minutes in bichlorid solution, 1 to 1000, and then washed off with salt solution. The field of operation is similarly prepared, except that the scrubbing is repeated daily for two or three days before the operation, and a soap poultice used at night. The instruments are boiled in soda solution for five to ten minutes, wrapped in towels or placed in metal boxes, which are opened only at the time of operation. Plain gauze is used for every purpose except packing the uterus, and in rare instances where drainage is used iodoform gauze is preferred. The silk ligatures are wrapped on spools and placed in glass boxes, and the silkworm gut and silver wire in long glass tubes and all sterilized by steam, as are the dressings. The plain catgut is boiled in alcohol and the chromicized is prepared after Edebohl's method. After the patient is placed on the table the dressing, which consists usually of plain gauze, is removed from the field of operation, and sterilized towels adjusted as usual. The instruments are unwrapped, and everything is in readiness. The sponges are used dry and thrown away when soiled. The flat sponges in the abdomen are also used dry, and are provided with a cord which is clamped with a pincette. The latter is left outside, so that the sponge can not be forgotten and left in the abdomen. The author has not had extensive experience in puerperal sepsis or general septic peritonitis, but would be inclined to use it in both these conditions, for it has proven satisfactory in sepsis following abortions and localized collections of pus in the abdomen.

SURGICAL SHOCK AND HEMORRHAGE, WITH REFERENCE TO PREVENTION AND TREATMENT.

This paper was read by Dr. Walter B. Chase of Brooklyn, N. Y., in which the author presented the following summary:

1. The treatment of shock should be preventive and curative, and to a large degree the indications for the former define the lines of treatment in the latter.

2. The proper exhibition of preventive measures includes a careful study of the functional activity and organic status of all important organs, and such treatment by hygienic, dietetic and therapeutic measures as will elevate the standard of bodily and mental health to a degree in which the maximum power of resistance may be produced and maintained.

3. Special emphasis should be given to lithemic and uremic excretion, and to the condition of the circulatory and nervous systems.

4. Knowledge as to inherited power of resistance to, and recovery from, serious disease and accidents, are of the highest value in determining the course of procedure and in estimating the chances for recovery after capital operations.

5. A supply of facilities and drugs for meeting all emergencies should be in constant readiness, with exact knowledge for the indications, dosage, physiologic and therapeutic effect of special heart tonics and stimulants, including strychnia, digitalis, nitroglycerin, etc.

6. Limit the time of an operation to the shortest space compatible with thorough work and proper technique.

7. Save the patient from the shock of fear to the utmost, and in selected cases proceed to operation without informing the patient of your purpose.

8. In shock with hemorrhage supply the volume of venous and arterial loss by direct transfusion of normal salt solution into the patient's veins.

9. Bear in mind the influence position has on the circulation under both shock and hemorrhage, especially in anemic conditions of the cerebrospinal nerve-centers and the heart.

Dr. W. H. Wenning of Cincinnati, Ohio, read a paper on

PLACENTA PREVIA WITH SPECIAL REFERENCE TO TREATMENT.

The following is a summary of the treatment laid down by the author in the order of time of the accident, amount of hemorrhage, and condition of the patient:

a. Before labor.—1. Hemorrhage slight, rest, expectant treatment. 2. Hemorrhage moderate; tampon vagina. 3. Hemorrhage profuse; also try tampon and induce labor.

b. In the beginning of labor.—1. Hemorrhage moderate; Braxton Hicks' method, provided the obstetrician has skilled assistance at hand, otherwise tampon the cervix with the cervical bag, until *c, labor is well in progress*, then rupture membranes and deliver by podalic version, or if hemorrhage is arrested by the descending head, deliver by forceps or permit spontaneous expulsion, if pains are good.

At any stage, when hemorrhage is excessive or can not otherwise be arrested, manual dilatation, followed by *accouchement forcé.*

The tampon is *indicated:* 1. In hemorrhage toward the end of pregnancy. 2. In the beginning of labor when the os is closed. 3. In moderate dilatation of the cervix—then use cervical tampon. *Contra-indicated:* 1. When dilatation is complete or nearly so. 2. When it fails to arrest hemorrhage even when dilatation is not far advanced.

Rupture of the membranes is *indicated:* 1. When the os is well dilated and either spontaneous labor or artificial delivery may occur. 2. When by this method hemorrhage is better controlled than by other means. 3. When in the absence of labor pains it will be followed by immediate pressure of the presenting part. *Contraindicated:* 1. When os is undilated and pains good. 2. In faulty presentation of the fetus unless it can be followed immediately by version.

Version is *indicated:* 1. When the os will admit two fingers and combined version can be readily made—Braxton Hicks' method. 2. When the os is well dilated or dilatable and hemorrhage is profuse, direct or internal version. 3. In desperate cases, *accouchement forcé. Contraindicated:* 1. When with a moderately dilated os combined version can not be skilfully made (the cervical tampon). 2. When with a well dilated os after rupture of the membranes the head immediately engages in the cervix.

In all cases strict supervision from the onset of labor to the end of delivery.

A paper entitled

COMPLETE HYSTERECTOMY AFTER INJURY DURING PARTURITION AND CÆSAREAN SECTION WITH REPORT OF CASES

was read by Dr. Joseph H. Branham of Baltimore.

The first patient was 24 years of age, female, married, and had been pregnant for the third time. As the pelvic contracture was so marked there was no hope of a living child being born naturally; the child was delivered by Cæsarean section. The patient lost considerable blood per vaginam after the operation and rapidly developed symptoms of septic infection. She died two days and a half after the operation. The question arose as to whether Cæsarean section or symphysiotomy was the better procedure. The essayist thinks the latter would have given the best chances for recovery, but as infection had already taken place, in all probability the final result would have been the same, and even craniotomy under the circumstances would likely have proved fatal.

The second case was one of rupture of the uterus. The mortality of this condition was said to be 80 per cent. The accident may occur at any time from the third month of gestation until the termination of pregancy. The causes and prominent symptoms of rupture of the uterus were detailed. *Treatment:*—When symptoms of uterine rupture occur, delivery should be completed as rapidly as possible by the use of whatever means may best bring about the results. The child nearly always dies in a few minutes, so that only the mother should be considered. If the child has escaped into the abdominal cavity immediate laparotomy is indicated. After the child had been delivered two methods of procedure are recommended by authority. One is the closing of the tear by packing with iodoform wicking and drainage of the parts with gauze. The other, which in complete ruptures is often more popular, is to do a laparotomy, cleansing the peritoneal cavity. In suitable cases close the tear by the Sänger method. If the tears are very extensive and there is a strong probability of uterine infection, a Porro operation or complete hysterectomy is the best method. The preventive method consists in the early relief of difficult labor by suitable operative interference, instituted before the uterus has become very thin and damaged by long continued pressure between the presenting part and the bones of the pelvis.

Dr. X. O. Werder of Pittsburg, read a paper on

TONIC AND SPASMODIC INTESTINAL CONTRACTIONS WITH REPORT OF CASES,

in which he reviewed five cases, one by Dr. Murphy, two by Dr. Long, and two of his own, reported by Dr. Long at the Richmond, Va., meeting of the Association, and adds some additional cases of a similar condition that he has observed subsequently. He referred to cases reported by L. Heidenhain and applied the term enterospasm, dividing the cases according to their nature and severity into spasmodic and tonic or tetanic forms. He considers that they are perversions of normal peristalsis due to a reflex chemical irritation exerted at the seat of contraction (either on the mucous or serous surfaces of the bowel) or elsewhere in the alimentary canal or abdomen, and shows that they assume surgical importance when, in the spasmodic varieties they simulate neoplasms as in three cases of that variety reported; or when they cause obstruction to the fecal current, becoming true cases of dynamic ileus, as in the five cases above referred to. Regarding the accuracy of diagnosis in these cases there can be but little doubt. Dr. Long's cases had undoubted symptoms of intestinal obstruction that varied in intensity over quite a long period. Operation revealed firm contractions of bowel. Careful search failed to show any other cause for the symptoms. Dr. Murphy's case previously treated for several attacks of lead colic, operated on for intestinal obstruction of several days duration, nothing was found but firm contraction of bowel. It relaxed after exposure to air. Three hours later spontaneous bowel movements occurred. Dr. Werder's first case gave history of previous attacks following ingestion of articles of diet made of milk. Simple salpingo-oophorectomy for simple sarcoma. Clean case. Excellent condition for first six days. Onset of attack sudden and followed ingestion of egg-nogg by an hour or so. Symptoms of partial intestinal obstruction that later became complete, plus depressing defects of some toxic agents, were noted. Especial attention was called to two rational but misleading symptoms, namely, the occasional expulsion of gas for first three days (that is till patient was in collapse two days before death), and an abdomen that was soft, flat, and not tense or tender. Violent peristalsis persisted till death. Autopsy four hours later showed peritoneum everywhere glistening, normal. Pedicle covered by normal endothelium. No adhesion; no exudate; nothing abnormal could be found except firm contraction of lower 55 cm. of ileum and whole large intestine, and sacculation of section of bowel next above it. Cause of contraction attributed, as a probability, to tyro-toxicon absorption; death of patient, to intensified absorption of tyrotoxicon and other toxins forcibly retained in bowel. His second case followed vaginal hysterectomy for small fibroid. Symptoms of obstruction began earlier and were more pronounced than in the preceding case. Peristalsis persisted till death at the end of the fourth day. Autopsy two hours later showed sigmoid and ileum adherent to vaginal vault for an extent of three inches. All peritoneum visible from above was normal in appearance. No exudate. Bowel extending from seat of adhesion of ileum to valve, and from adhesion of sigmoid to anus, firmly contracted. Sacculated bowel above. Plastic lymph at seat of adhesions and at the parts exposed to vaginal gauze and clamps. Two c.c. of fluid found there. No pus visible to naked eye. No microscopic examination. Cause of contraction, chemical and mechanical irritation applied to serous surface; cause of death, possibility of mild sepsis combined with absorption of toxin from intestinal canal.

Of the spasmodic variety, the first case showed a sausage-shaped mass, three inches long and one inch thick at pylorus, with limited mobility, and mapped out at each examination by several careful observers—not present when under ether and abdomen cleansed. Abdomen opened, pylorus and duodenum delivered; looked and felt normal. On manipulation they contracted firmly and were as hard as a finger, but only to relax in two or three minutes. This was repeated several times in full view of all present. In second case, contraction found accidentally when doing a supensio-uteri. In third and fourth cases consulted for presence of tumor. Found firm contractions of bowel, near umbilicus, that resembled a neoplasm. They relaxed and contracted again several times during an examination that lasted fifteen or twenty minutes, always reappearing at the same place. Condition recognized and operation advised against. These patients were all neurotic and complained of quivering and commotion at seat of trouble, as well as of dyspepsia and obstinate constipation.

DYNAMIC ILEUS FOLLOWING OPERATIONS INVOLVING THE ABDOMINAL CAVITY, WITH REMARKS ON ADYNAMIC ILEUS.

This paper was read by Dr. **Frederick Blume** of Allegheny, Pa. The author said that considerable progress in the diagnosis and treatment of ileus following abdominal section was made when Olshausen in 1887 directed attention to an article read before the Berlin Obstetrical and Gynecological Society, to the form of intestinal obstruction which had not yet been recognized, viz., a paralysis of the gut not depending on septic peritonitis. The symptoms in these cases are increased, pulse rate normal, slightly elevated, or, in some cases, subnormal temperature and vomiting. Two or three days after the performance of the operation, or even later, symptoms of collapse manifest themselves, the pulse becomes rapid and feeble, the abdomen more and more distended and retching and vomiting more frequent. Neither gas nor feces are expelled from the rectum. Death ensues between the fourth and tenth day, and is the result of general systemic intoxication from absorption of the decomposed intestinal contents.

In a recent article Engström reviews the literature of the subject, and concludes that paralysis of the intestines can and does occur after operation involving the abdominal cavity without infection having taken place at the time of operation. Eventration and prolonged manipulation of the bowel are the most potent etiologic factors, causing irritation of the nerves of the mesentery and gut wall, and leading to changes in the circulation. From his own experience Engström is able to confirm the statement of other observers that a paresis of the intestinal wall can be produced by the administration of strong saline purgatives, and it appears to be by no means improbable that, as a consequence of their use, a weakened condition of the gut walls is produced prior to the operation. He looks upon the increased susceptibility of the nervous system, often so marked in patients about to undergo a surgical operation, as a predisposing etiologic factor.

The author said that the differential diagnosis between postoperative intestinal obstruction and dynamic ileus is practically impossible, but that in either case the only chance for the patient is afforded by early operative interference. The surgeon, however, must distinguish these forms of ileus and a very obstinate form of constipation so often met with and so difficult to overcome, after operations in the abdominal cavity. The occurrence of fecal vomiting is not always a pathognomonic sign of ileus, as this vomiting sometimes occurs in other conditions and when there exists no indication for surgical interference.

Dr. **Albert Goldspohn** of Chicago contributed a paper on

THE FATE OF OVARIES IN CONNECTION WITH RETROVERSION AND RETROFLEXION OF THE UTERUS.

He drew the following conclusions: 1, In all cases of retroversion and retroflexion of the uterus a knowledge of the ovaries as to their location, mobility and general physical condition should comprise an essential part in the diagnosis, as determining largely the nature and urgency of the treatment. 2. The welfare of ovaries, in general, demands such a degree of anterior inclination of the longitudinal axis of the uterus as will enable intra-abdominal pressure to bear upon the posterior surface of the organ, and thereby to act in unison with its other supports to retain it and its adnexa in normal position and function. 3. Inasmuch as in the female pelvis, as well as elsewhere in the human body, the natural and considerable abilities of healthy tissues to defend themselves against microbic invasion (infection) are lowered or annulled in direct proportion to any degree of mechanical embarrassment of the venous circulation in the tissues or organs, it behooves gynecologists especially to be alert in recognizing and correcting all material anomalies in place or posture of the female generative organs or in securing to them their normal freedom.

Dr. **Walter B. Dorsett** of St. Louis, Mo., read a paper entitled

THE ADMINISTRATION OF PHOSPHATE OF STRYCHNIA DURING GESTATION.

The following observations have been made by him in the use of this drug during the gestation of weak and debilitated patients: A good appetite and good assimilation are obtained in the general weakness and debility of the anemic. Constipation is relieved, the patient is built up and placed in a good condition to pass through the ordeal of labor. The uterus contracts promptly after the third stage of labor, and the use of ergot is entirely dispensed with. If he finds it necessary to use the forceps, the patient is given a hypodermic injection of 1-30 grain sulphate or phosphate of strychnia as soon as the anesthetic is commenced, but no ergot is ever used. After the continuous use of the phosphate of strychnia, the uterus contracts promptly after the second stage of labor, and in many cases the application of Crede's method of expression of the placenta is not needed to bring it away, and no postpartum hemorrhages have occurred. The frequently observed chilliness or rigors, which in the majority of cases follow labor, has been noticed in but few cases. He has used strychnia for some time in his abdominal surgery, for the purpose of preventing shock and to control the pulse in the operations, and in this way was led to its use in obstetrics. As phosphorus and strychnia are remedies used in the treatment of rachitis with good results, would it not be the remedy during the gestation of the rachitic fetus?

Third Day—Afternoon Session.

This session was largely devoted to the exhibition of pathologic specimens, with histories and photographs of the same. Specimens were presented and the histories of cases related by Drs. Vander Veer, Dorsett, Macdonald, Ross, McMurtry, Smith, Hughes and others.

Fourth Day—Morning Session.

Dr. **Geo. S. Peck** of Youngstown, Ohio, read a paper in which he reported

FIFTY-TWO CASES ILLUSTRATING HIS PERSONAL EXPERIENCE WITH THE MEDICAL AND SURGICAL TREATMENT OF APPENDICITIS.

He said there were four cardinal symptoms which will almost invariably insure a correct diagnosis, if they occur in the order given. 1. Sudden severe pain in the abdomen, generally of a colicky nature, located in any part or extending over the entire abdomen. 2. Always nausea and frequently vomiting. 3. Increased temperature. 4. Localized tenderness in the right iliac region. Some patients will have diarrhea, while others may be constipated. He had never failed to make a correct diagnosis when the four cardinal symptoms were present.

Treatment.—Surgeons differ in their methods of operating. Some advise in the acute suppurative form simple incision and evacuation of pus. If the appendix can not be easily found, it should be left, drained and packed, and then in the interval between attacks the appendix should be removed, always provided one can get the consent of the patient, which the speaker has found to be difficult. A few surgeons advise the liberation of all adhesions and the removal of the appendix in all cases of acute suppurative appendicitis and have reported good results. He believes it is the duty of every surgeon to make a complete operation in the vast majority of cases, and thinks that the time is not far distant when surgeons will advise the breaking up of all adhesions, the removal of every diseased appendix, and the closing of the incision as is now done in the operation for pyosalpinx, as advised by Morris, Price and McMurtry. In his last three cases he has followed this method and the results have been far beyond his expectations. Two of the cases were discharged in three, and one in four weeks.

Dr. **Lewis S. McMurtry** of Louisville, Ky., followed with a paper entitled

THE OPERATION ITSELF IN APPENDICITIS.

He considered the subject under the following headings: 1. The incision. 2. Dealing with adhesions and with abscesses. 3. Removal of the appendix. 4. Drainage and isolation of the peritoneum by gauze.

Concerning the incision three important considerations must be observed: 1. To obtain easy access to the caput coli with sufficient working space. 2. To secure all natural advantages to facilitate drainage. 3. To do the least damage possible to the parietal structures incised in order that firm union may be secured and hernia thereby prevented. The early operations for appendicitis were mostly in extreme cases, wherein suppuration had obtained, and consisted in cutting down into an abscess and evacuating and draining the same. For this purpose the vertical incision was adopted and is yet practiced by many surgeons. This incision does not, however, give as easy access to the appendix and to the outer and posterior areas adjacent thereto, which are so frequently involved, as does the oblique incision. A method of dividing the abdominal wall by a combination of incision and blunt dissection has been described by McBurney and commended by many writers on the surgery of the appendix. This incision was described at length.

Dealing with adhesions and abscesses. In dealing with adhesions and abscesses the same general rules of surgical treatment should be observed in appendicitis as in similar conditions affecting other organs enclosed within the peritoneum. Whenever practicable, adhesions should be separated, abscesses emptied, disintegrated structures composing foci of infection removed, and cleansing and drainage secured by measures of assured efficiency.

Removal of the appendix.—In his early operations he ligated the appendix with the meso-appendix, using fine sterilized silk, cut away the appendix and applied pure carbolic acid to the stump. Later he adopted the modern method of transfixing the meso appendix at its base, cutting it away, stripping back a cuff of peritoneum from the appendix down to its junction with the cecum, ligating the appendix with fine silk and cutting it away, sterilizing the stump, invaginating the stump into the cecum and covering with peritoneum by careful stitching after the Lembert method. Nothing in the progress of healing or in ultimate results indicated any advantage of the latter method over the former simple ligature, excision and cauterization.

Finally, Dr. McMurtry discussed drainage and isolation of the peritoneum by gauze.

Dr. THOMAS J. MAXWELL of Keokuk, Iowa, contributed a paper on "Senile Irritable Uterus." In three cases he was unable to relieve this condition by tentative treatment, and finally resorted to hysterectomy with complete success in all of them.

The election of officers resulted as follows:

President, Dr. Charles A. L. Reed of Cincinnati, Ohio; *Vice-Presidents*, Dr. Richard Douglas, Nashville, Tenn. and Dr. Walter B. Dorsett, St. Louis, Mo. *Secretary*, Dr. Wm. Warren Potter of Buffalo, N. Y. *Treasurer*, Dr. X. O. Werder of Pittsburg, Pa. Place of meeting, Pittsburg, Pa., September 20, 21 and 22, 1898.

After introducing and adopting resolutions of thanks for courtesies extended, the Association adjourned.

SELECTIONS.

Centrilobular and Pericellular Cirrhosis.—Dr. J. E. Adami, in the *Montreal Medical Journal*, concludes a long article on cirrhosis with remarks regarding these two interesting phases of hepatic disease. The centrilobular form apparently only develops as a consequence of chronic heart or lung disease associated with passive congestion of the liver and the condition of nutmeg-liver. Passive congestion in general may lead to fibroid overgrowth originating around the veins, and it is around the central intralobular branches of the hepatic vein that such fibroid overgrowth may at times be recognized. While sundry French observers would ascribe one form of hypertrophic cirrhosis to this central development of fibrous tissue, it is difficult to agree with them. The liver of passive congestion may be larger than normal but congestion is not hypertrophy, and associated with any degree of centrilobular cirrhosis there is marked hypertrophy of the liver cells, while the amount of connective tissue laid down is relatively slight as compared with what may be developed in perilobular cirrhosis. It is unfortunate that this term, hypertrophy, has been introduced at all in connection with cirrhosis. This form also is incapable of being recognized clinically; it may be suspected in long-continued obstructive disease. It is in every respect one of the minor forms. Regarding pericellular or replacement cirrhosis, I would say, that while I am inclined to think that in portal cirrhosis there is primarily an overgrowth of connective tissue around the medium-sized branches of the portal veins and recognize a similar deposit occurring around the bile ducts, arteries and branches of the hepatic veins, there is another highly important deposition or development of new connective tissue in the liver which yet remains to be discussed, one which has up to the present received too little attention, although from to time high authorities such as Kelsch and Wannebrouck, Hamilton, Beale and Grandmaison have more or less called attention to it. Where isolated cells of a tissue or collections of cells atrophy and die there is in general an attempt to replace them, if not by cells of a similar nature, then by connective tissue, or, failing this, by fluid, (as in some cyst formations). A replacement fibrosis of this nature may be localized, as after scattered necroses through the liver substance. Such fibrosis very possibly explains in part the cirrhosis occurring in malaria, and in those infectious and septic diseases in which sporadic necroses of the liver are becoming more frequently recognized. Or on the other hand, it may be more generalized, affecting the periphery of the lobule or in some cases the whole lobule. In the Pictou cattle disease this could be seen in its various stages. Pictou cattle disease is a chronic infectious disease of cattle in Nova Scotia characterized especially by extensive cirrhosis of the liver. In early cases, as first pointed out by Dr. Wyatt Johnston, the liver cells show various evidences of degeneration, and this stage is followed by atrophy so extensive that in advanced cases all the cells of some lobules may become unrecognizable, their place being taken by a delicate connective tissue. In other regions, short columns of the atrophied cells may be isolated and surrounded by similar connective tissue, while, as in biliary cirrhosis, there may be very numerous imperfectly formed bile canals, examples of which have been termed "reversionary" degeneration of the liver cells. Along with this there is in general singularly little small-celled infiltration. The process is essentially one of hypertrophy of the liver cells by toxic agency followed by replacement fibrosis. It is interesting to note that in all cases where this pericellular cirrhosis is well marked the liver tends to be enlarged—hypertrophic—or if not enlarged is not found hobnailed. There appears to be a difference in the way in which the new connective tissue is laid down. Whereas in ordinary portal cirrhosis there is a frankly inflammatory infiltration of small round cells, followed by connective tissue growth, the new tissue is typically cicatricial, *i. e.*, with full development it contracts very markedly, and so produces the hobnailed condition. In such cases the atrophy of the liver cells is secondary and is in the main due to the presence of the fibrous bands. In the cases of extensive replacement cirrhosis above referred to, there is curiously little small-celled infiltration; a loose transparent connective tissue develops which evidently is not nearly so prone to contract. Degeneration and atrophy of the liver cells may be brought about in four ways: 1. By pressure. 2. By toxic substances reaching the cells by the circulation. 3. By toxic substances reaching them along the bile capillaries. 4. By arrest of function resulting from obstruction of the bile ducts. To the first of these we have already referred; the contraction causing the atrophy does away with the opportunity for a replacement fibrosis. About the third possible way we know little. It is unlikely that toxins should diffuse up the bile canals in a direction contrary to the flow of bile. With regard to bacteria penetrating the liver along the bile ducts and producing toxins we are in doubt. We know from the researches of Welch, Flexner and others, that pathogenic microbes are not infrequent in the gall bladder, and in the last two cases of hobnailed liver coming to the postmortem room of the Royal Victoria Hospital we were not a little surprised to gain cultures of the B. coli communis (the most common form to be found in the gall bladder) from the liver juice when other glandular organs did not show this form. But on the whole it is for the present to be regarded as unlikely that degeneration of the liver cells and cirrhosis are induced to any considerable extent by toxic agencies passing up the bile duct and capillaries. It would seem more probable that obstructed and perverted action of the liver cells by closure of the bile ducts, leads to their degeneration.

The Great Lessons Taught by Bacteriology.—Dr. Sims Woodhead, pathologist at the laboratory of the Royal College of Physicians, London, in a recent lecture reported in the London *Lancet*, seeks to correct certain false notions that have arisen regarding the life work of the bacteria. The tendency has been to accept them as the ultimate causes of certain forms of deadly disease and as promoting the evolution of putrefactive products; whereas, as a matter of fact, they are instrumental in keeping the world sweet and clean for its inhabitants and in maintaining a constant circulation of organic matter from the dead condition to the living and from the living to the dead. It is interesting to reflect that without the aid of bacteria the human race would be unable to continue its existence, the animal and vegetable world would long since have perished from sheer inanition or starvation, and the work of the world as a great laboratory would have come to a standstill. Bacteria, as is being found out every day, may be engineered for man's good, so long as they are kept under intelligent control, and once their habits are understood they prove to be the most perfect servants that can be obtained. The lecturer proceeded to trace the history of bacteria and their discovery, and the developments up to the present time which have followed upon a close and exact study of their behavior. The functions of bacteria in the great natural processes in their bearing upon sanitation were then dwelt upon; and finally, the recent developments in regard to the wonderful ability of certain species of bacteria to appropriate the nitrogen in the air, through the medium of the soil, for the maintenance and the sustenance of leguminous plants, formed not the least interesting section of the lecture. It was remarked that so well defined were the results of the researches in this direction, that cultivations of these organisms are now made for sale and kept in closed bottles for distribution to all parts of the world. There, when mixed with water and thrown over the soil, they immediately begin to do their work, and taking nitrogen from the air, which lends valuable assistance to that from the soil, they enable the plants, and especially those requiring large quantities of nitrogen for their full growth and development, to grow both more rapidly and more luxuriantly than they could do if unaided by this supplementary store. The relation of bacteria to disease was next touched upon, and the beneficial effects of fresh air and light accounted for by observations on the inhibitory action of these agencies upon such organisms. Dr. Woodhead concluded his lecture with the following words: "As yet no one can say that we have reached even a resting stage, and it behooves all those who desire to see advances made in the treatment and prevention of disease—whether in the department of protection and cure, with which medicine is specially concerned, or in the preventive department, with which civil engineers have to deal—to continue to follow closely every new fact and every fresh theory arising out of new observations, in order that bacteria and the forces with which they are endowed may be made our well disciplined servants, instead of being allowed to waste their energies as our uncontrolled and uncontrollable masters."

The Practitioner's Economies in Time and Effort.—The physician who hopes to accomplish much, who has the ambition to do something more than routine medical work, who wishes to keep abreast of the times, must learn not only to seize the day but the hour and minute of leisure. The secret of accomplishing much consists in having convenient arrangements for utilizing the scraps of time between professional engagements and in being able to make light of drudgery. Convenience means the performance of many things; inconvenience, the neglect of necessary tasks. The average man will examine urine if his utensils are in or next to his office and if he has a sink into which to throw waste. If he must go up or down stairs for his examinations or to empty bottles, or if he must push aside writing materials to make room for his test tubes, he will avoid analysis of urine as much as possible and will fail in diagnosis in occasional cases. In writing, a typewriter will be found easier than a pen or pencil. Hour for hour, more can be written and with less fatigue in spite of the greater amount accomplished. A roomy and well arranged desk is a great time-saver. Have a drawer for each line of work that you happen to be engaged in, one for business, one for science, one for correspondence; set aside a space for every important undertaking that will occupy spare moments for more than a few days; in short, have your notes or letters, or whatever your material may be, so that you can pick them up and lay them aside at a moment's notice. Personal comfort is a great factor in increasing one's capacity for work; perhaps it should even be placed before convenient arrangement of materials. Spare your eyes, use a good lamp instead of gas and make sure of plenty of daylight, not too glaring. Place your furniture so that the light will not be in front of you. All things considered, your private office ought to be the best room in the house, for its purpose. Keep warm, avoid drafts, don't stifle for lack of ventilation in summer. If only one room in your house fulfils these demands, take it for the office. You can put up with imperfect hygiene in the parlor or even in the dining room, where you will spend only a small part of your time. Have an easy chair, well cushioned, and preferably one that you can adapt to the height of your desk. In general, make your office as pleasant, as convenient, as comfortable as possible. Use your brain to the best advantage and not too long on any one task. If your professional work for one day has been mostly in the open air, rest yourself by reading or writing, or chemic or microscopic study. If most of your patients have been office cases, and the day is pleasant, refresh yourself by attending to the numerous errands that are always in order. Tax your memory as little as possible with unnecessary details. Keep one of the memorandum blanks which are sent you as an advertisement early in the year, and whenever an engagement is made, jot it down under the proper date. As you pay your life insurance premium, or attend a meeting or deliver a lecture, or discharge any other recurring obligation, enter the next in your list. It will take but a moment to consult your memoranda each morning, and you will be free to forget engagements till the proper time and need not worry about the possibility of mistakes.—*American Therapist.*

PRACTICAL NOTES.

Objections to Use of Picric Acid.—Dr. Waldo (*Lancet*), commending upon the growing use of picric acid in eczema, thinks that "it may cause much prostration, and in fact all the symptoms of carboluria, with very dark urine. The unpleasant symptoms developed certainly resembled the action of carbolic acid."

Thread Worms.—Some of our exchanges recommend the formula of the *Journal de Médecine de Paris*: Three-fourths of a grain of santonin and one and a half grains of calomel by the mouth every day before breakfast for three days; also every evening for the same number of days insert within the sphincter a modicum of mercurial ointment one part and glycerite of starch, two parts.

Diabetes Among Locomotive Engineers.—The *Medical Press and Circular* refers to the increase of cases in this disease and especially to its marked mortality among the class mentioned. The causes cited are the jarring, the mental strain and the changes of temperature. "There is much yet concerning the pathology and etiology of diabetes which is obscure;" so concludes the article.

Tuberculin Test for Infants.—G. A. Alfaro of Buenos Ayres, urges the more general use of the tuberculin test in diagnosing the affections of infants and young children. It is absolutely harmless at the minimal dose and at intervals of a week or more, while the benefit derived from it is very great, as he demonstrates by several observations in the *Anales del Circulo Med. Argentino.*

The Meningeal Symptoms in Typhoid Fever, according to Dr. Kuehnau (*Berliner klin. Wochenschrift*) are due to a metastasis of the typhoid bacillus, as proven in a case where its presence was manifest in the mesenteric gland, spleen and exudation over the convexity as well as at the base of the brain. Death occurred on the thirty sixth day during profound coma. The ulcers were nearly all in process of healing although the bacilli were still present in Peyer's patches. An examination of the blood during life revealed colonies [illegible] the [illegible], showing the cause of distribution.

Sulphonal in the Night Sweats of Phthisis.—Combamale and Descheemaker (*Revue de Therapeutique Medico-chirurgicale*), except in the very advanced stage of tuberculosis when effect is merely negative, give from fifteen to thirty grains of sulphonal each night for the night sweats.

The Carasquillas Treatment of Leprosy.—The International Executive Commission of the Pan-American Medical Congress is advised, through Dr. I. M. Calnek of San José member for Costa Rica, that the government of that country some time since commissioned Dr. Elias Rofas of San José to go to Bogota, Republic of Colombia, and study the treatment of leprosy according to the method of Dr. Carasquillas. After careful study of the disease itself, of the treatment and its results Dr. Rofas returned to San José and reported favorably to his government. The treatment has been applied in one case of tubercular leprosy in Costa Rica and the patient has improved.

An Iron and Quinin Tonic Without the Tannate of Iron Precipitate.—G. Patein has a study of Martial medication in chlorosis (*Nouv. Remèdes*, July 24), endorsing it in general, given with moderation and as indicated. He rejects a number of the preparations in vogue but approves of protochlorid of iron (pills containing 0.10 gram ferric chlorid), and also of iodin of iron, especially for struma and lymphatic conditions. He has found that glycerin prevents the formation of tannate of iron and gives the formula of a tonic as follows: Tartrate-ferrico-potassic, 10 grams; extract of quinin, 10 grams; glycerin, 20 grams; aq. dest., 10 grams; Madeira wine q. s. to make 1 liter. He considers mineral waters a good supplement to increase the amount of iron taken with the food.

The Causation of Puerperal Eclampsia.—The nephritis which coexists with eclampsia is mainly secondary and analogous to nephritis of scarlatina. The liver deals more rapidly with the nitrogenous products of metabolism than with the non-nitrogenous moiety. The authors suggest that in pregnancy the increased work thrown on to the liver may result in hepatic inadequacy and that there may be a "liver of pregnancy" just as there is a kidney of pregnancy. The products of metabolism in both fetus and mother are carried to the maternal liver where they normally undergo katabolic changes to urea and bile salts; but in cases of hepatic inadequacy these products accumulate and eclampsia results. Strumpf found acetone in the urine of all eclamptic patients, whose breath smell of it. The relation of acetone to metabolism is so important that the urine of pregnant women should be systematically examined for it.—*American Journal of Obstetrics*.

A Case of Gonorrhea in a Girl of Twenty-six Months old.—Dr. Alfred Hinde of Chicago, reports the following: Under my charge at present is a girl of two and one-half years of age who was referred to me because of an obstinate catarrhal conjunctivitis of each eye. In appearance there was nothing unusual in the eye disease, but on questioning the mother the fact developed that the child had had a vulvar discharge for four months. On examination this was found to be profuse and purulent. Slides were taken of the eye and vulvar discharges, stained and examined, and in the eye slides the ordinary microbes were alone found; but in the vulvar slides a large number of gonococci were present in each one. A leucorrheal discharge in the mother was found to contain a few gonococci, and the father was said to have contracted a typical gonorrhea one year ago which had resulted in a marital separation at that time.

Radical Cure of Prostatism.—R. Macias attributes the troubles known as prostatism to exuberant growth of the gland compressing the urethra, or extending into the bladder with more or less irregularity in the size of the canal left for the passage of the urine. He treats the former condition by inserting the largest catheter possible without injury, guiding it with the index finger in the rectum, and then incising down to it with a bistoury. An Otis urethrotome is introduced and the incision made as indicated. The forefinger is then inserted and the condition of the bladder explored. If nothing is found there the operation consists merely in scraping off with the finger nail, the protruding growths of foci, of suppuration, concluding with the use of small curettes. This is usually all that is needed in all but senile cases. When the exuberance rises into the bladder he incises and removes the tumor with the electrocautery inserting the wire with a sharply curved needle on a handle, cutting the growth into quarters and pediculising each quarter for its final extirpation with the wire introduced with a straight blunt needle at the base close to the cervix. The *Revista de Anat. Pat. y Clin.* July 1, contains a full, illustrated description of the process and instruments as presented at the Second Pan-Amer. Congress.

Avulsion of the Uterus and Adnexa; Recovery.—The following case of avulsion of the uterus is reported by Dr. E. Hickson Smith, in the London *Lancet*. The recital is substantially thus: The patient gave birth to a child while on her hands and knees on the floor. The midwife some two hours afterward, having separated the child, etc., found a lump protruding which she mistook for the head of another child and pulled upon it for three quarters of an hour until she had dragged it away. Dr. Smith on arrival found an inverted uterus, which he turned back again. This proved to be the whole of the uterus and cervix with its peritoneal covering and one broad ligament with fallopian tube, but minus the ovary. The broad ligament of the other side was congenitally absent. On inserting the finger into the vagina, it moved freely about among the intestines, and the absence of the uterus and cervix was distinctly apparent. Hemorrhage was slight. To avoid prolapse of the bowels and general peritonitis, recourse was had to decubitus, an antiseptic plug, morphia and a strictly milk diet. The peritoneum closed up and the top of the vagina cicatrized over, the patient being able to go about in three weeks. Three months later a professional call found her in her usual health and the vagina a *cul-de sac*.

Eucain Hydrochlorid in Rhinolaryngology.—Zwillinger in *Pesther Medico-chirurgische Presse* states his preference for the above over cocain, although the latter yields an intenser and more permanent anesthetic effect. His experience with eucain in rhinologic work has been only such as is obtained by painting the mucous membrane with a solution of the drug. That eucain has less disturbing effects than cocain has been the general report, but that it is not wholly free from by-effects is seen from the following: Eucain itself, however, possesses unpleasant by-effects which may limit its employment for affections of the nose and throat, but to what extent it is impossible to say. These by-effects consist in a burning sensation, which even in very dilute solutions occurs at the place of application. In nearly every case patients make more or less mention of the irritation which is accompanied by copious water secretion from the nasal cavity. The hyperemia caused by eucain, slight as it is, may also limit its use in some special cases; but on the other hand, the fact that it produces no ischemia increases the value of the preparation in the therapy of other nasal diseases. As regards the permanency of the solution, eucain possesses a great advantage, as it keeps well, and can be sterilized with boiling, without decomposition. The conclusions to which he has arrived are as follows: 1. The 2, 5, and especially the 10 per cent. aqueous solutions of eucain, produce such a degree of anesthesia when applied to the mucous membrane of the nose, throat or larynx that local operations can be carried out without the slightest pain. 2. The quantity which suffices to anesthetize the mucous membrane is completely innocuous. 3. The employment of eucain in diseases of the nose or throat is only limited by the slight irritation caused by the solution upon the mucous membrane, and also by a slight hyperemia which it causes.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location. Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, SEPTEMBER 4, 1897.

THE ARMY EMERGENCY RATION.

The emergency ration established by G. O. 49, Hd. Qrs. of the Army, A. G. O., Washington, D.C., Dec. 5, 1896, has recently been subjected to a practical test in the field, the results of which have been reported as entirely satisfactory. This is to be appreciated the more because we have in vivid remembrance the disastrous results of a test made in the Department of the Colorado of an emergency ration suggested by the officers of that department. The test of the War Department ration was made by troops from Fort Sill, Oklahoma Territory because on account of the absence of settlers, on the Indian reservation, a command could march for the required number of days without having to camp or to pass within twenty or more miles of any settlement where the troops might obtain any article of food unknown to their officers. Deputy Surgeon-General SMART was ordered from his station in Washington, D. C. to accompany the command and to report on the condition of the men before, during and after the march. The report of the commanding officer of the troops has already been published in the military journals and from it has been learned the successful issue of the expedition. This is of the highest importance from the military point of view, because it demonstrates the ability of a cavalry or infantry command to cut loose from transportation for ten days and marching by by-ways or even by compass to seize an unguarded position or make an unexpected attack on the enemy. But we are not concerned at the present time with the military results. Dr. SMART's report to the war department has been rendered but will probably not appear in print until the publication of the annual report of the surgeon general of the army in September next. We have learned, however, some of the conclusions reached by him as the result of his observations.

The expeditionary command consisting of two officers and forty-four men engaged in active field service on the emergency ration, while a control experiment in the form of one officer and nine men on full field rations made similar marches on parallel lines but beyond communicating distance. The question at issue was: Would the limited emergency diet satisfy the men, many of them young and untried soldiers, and enable them at the end of ten days of active field work to meet an enemy or be available for a continuance of active field service? The record shows that the command lost in weight an average of 2.935 pounds per man, but part of this loss was due to the change of conditions from garrison life to active field service, for the men of the control experiment, with as much as they desired to eat, lost an average of 1.35 pounds per man; but the loss of weight of the emergency command was not associated with any loss of strength, for the dynamometric pull was twenty-four pounds greater per man at the end than at the beginning of the experiment. In fact Dr. SMART is reported as having said that the command returned to Fort Sill in better training and athletic condition than when it started out from that post, "and as I am confident that I myself could have started out that day and repeated the ten days' experiment I am confident that every soldier in the troop could have done so."

The emergency ration was intended to constitute a maximum diet for hard labor. It consists of those articles of food supply with which the soldier is familiar, as emergencies are not the times to make any material or experimental changes in his diet. The limit to be carried on the person or horse was announced as five days' rations, because emergencies would seldom last longer than that period; and, therefore, during the majority of emergencies the soldier would have the benefit of the most generous diet; but should an emergency require it the five days' rations were expected to be economized and to last for any number of days not exceeding ten. It was conceived that if an emergency lasting ten days should occur it would be one of extreme gravity and of such a character as to call for self-sacrifice on the part of the troops. When thus made to last for ten days the men were reduced to live on what is called subsistence diet. a diet sufficient for the repair of the waste incidental to the carrying on of the vital processes but leaving all work productive of external results to be effected at the expense of the tissues of the individual. When used in this way the daily allowance per man consists of ounces of hard bread, 5 of bacon and 2 of pea meal with coffee, saccharin, salt, pepper and tobacco. This is equivalent to protein 2.128 ounces, fat 3.809 ounces and carbohydrates 6.93 ounces, a total of 12 867 ounces per day, furnishing 147 grains of nitrogen, 3,159 grains of carbon and an energy equal to 2,055 calories. The daily newspapers speak learnedly of chemic and concentrated foods, thirty pounds of which will suffice to sustain a man for a year. There is before us at the present writing an editorial in a city daily to this effect in connection with the journey to the Klondike mines. The information concerning these chemic foods is derived from the advertisements of food manufacturers; but these have no basis in physiologic science.

On the limited ration above stated, Dr. Smart found, by the daily use of the scales, that young men lost more of their weight than older men, that short men lost more than tall men, but that heavy men lost proportionately more than the lighter weights. He holds, however, that the manner in which the men utilized their ration of bacon had much to do with loss of weight. Some fried it to a crisp, tilting the melted fat into the fire and thereby losing more than two-thirds of its value. Others fried their hard bread, previously softened in water, in the melted grease and thus saved some of the hydrocarbon. Others, again, chopped their bacon into dice and boiled it in their pea soup, thus utilizing the whole of it. As to the frying of the softened hard bread in the melted fat, Dr. Smart remarks: "I am aware that this practice is denounced by most authorities on dietetics, but I have yet to discover in a very extended experience any harmful effects from this method of cooking, either among healthy young soldiers or hardy old soldiers." It would seem that when the system is on short allowance it is ready to utilize food supplies however presented.

On this diet which, although less in weight than the subsistence diet of the physiologists, has a higher energy from its larger proportion of fat, some of the men gained in weight. It is evident, therefore, that the subsistence diet of the physiologists is overestimated; that men can live and work and be strong on a much smaller quantity of food than is usually considered necessary, and that, in fact, the amount of food generally used is far in excess of that required by the necessities of the human system.

This experimental march reported by Dr. Smart has also a financial aspect which is of considerable importance and which requires only to be mentioned to be appreciated. The two officers and forty-four men of the emergency ration command lived an active life on a ration, tobacco included, which cost only about 9 cents per man per day.

Let us have a Department of Public Health!

THE FATE OF THE IDIOT.

There are in the United States about 95,000 beings hopelessly idiotic. Their existence and care is a problem perplexing alike to the sociologist, the political economist and the physician. It is beyond question that the simple endurance and perpetuation of this load of useless misery that has been habitualized by our modern civilization might and should be settled in a somewhat different way. Of what use to humanity, to civilization or to science, is it to go on as we are at present going? There is no truth so well established by history and by general biologic science as that the evolutionary process has been brought to its present position by a plan utterly different from that which we have adopted with our idiots. It is also plainly, painfully clear that the economic moral is no less striking and manifest. For every three or four of these wrecks kept alive by our sentimentalism one laborer's life must be continually sacrificed.

May we safely, do we wisely, reverse the universal biologic law as we are doing? Are we wiser than the cosmic process—call it God, or evolution, or what we please—and what if any are our real reasons, our unconscious motives, and what compensations may then be for our apparently illogic method? The writer has long pondered these problems, weighed the obscure and halting answers that have been hesitatingly advanced, has sought to give due allowance to the full importance of the religious and emotional, the psychologic aspects, and the possible baneful results of the obviously suggested natural method of riddance; as a result he can reach no other conclusion than that our duty to the future, to humanity, to the profession, and to the idiot himself is that, under law and publicity, and by a properly appointed commission the hopeless idiot should be put to death; and for these reasons:

1. In the consciousness of each one of us we are well aware that were we that being every dictate of kindness, every desire of our sane-minds, would demand that those in charge of us should not curse us with a continuance of life. We recognize that to us it would be cruelty, not kindness, to thus condemn us to such a hideous travesty of human existence. The psychologic argument is clearly pronounced.

2. Every parent of an idiot-child acquiesces, nothing more, in the present arrangement, but in his heart of hearts—the hopelessness being admitted—he wishes that his child should not thus be doomed by the mere unconscious vegetative processes of the body, and by a false sentimentalism upon our part, to a loathsome *reductio ad absurdum* of parenthood The genealogic argument is quite as definite as the rational.

3. It is unjust to the present-day laborers to compel them by thousands to give their life-work to nourish and house and care for these things whilst the poor and would-be self-helping, the slum-children, the unlucky,

the unsuccessful, are dying about them because of the lack of the care given to and wasted upon the idiot. The economic lesson is as plain as the two preceding ones.

4. It is unjust to these unfortunates struggling for healthy and useful life and with every promise of hope in them, to give our superfluities to the ungrateful, unconscious, hopeless idiot. The ethics of the matter are likewise plain.

5. The religious feeling must take the same position. The soul of the idiot is certainly gaining no experience in its sad plight that can be of use to it in the future. Keeping it here only postpones a desirable beginning of education and progress.

6. It is unprofessional to do otherwise. This may at first seem strange and untrue, but it is really not so. Our duty of course is to cure disease—aye, but not to perpetuate it! At least it may be said, to ease and soften the end of disease in inevitable death. Ah, yes, but note the essence of the distinction: We are not to professionally establish a system for perpetuating the disease, doing nothing either for cure or for oncoming death. In our last sad offices euthanasia is a duty of our art when it is forced to renounce all possibility of help. Let it, then, be so here.

The whole argument turns upon the incurability of the disease, the utter hopelessness of any return to normal-mindedness. For all that makes life valuable the permanent idiot is already dead, because mere life of the body with worse than death of the mind, adds the horror of death-in-life, a fearful caricature of genuine life, not good either to the sane or to the insane sufferers who endure and support it.

In insanity there is hope, or possibility, however *remote, of recovery. In incurable bodily disease there* is the mind above it useful either to self or the world in some remote way. In every other type or example of disease there is a like element to give pause to other motives. And at least and at last everywhere else there is some possible lesson to be gained psychologically or pathologically by the scientific-minded student. But in the idiot it is not so, or but most rarely so. What lessons have we derived or are we seeking to learn from a scientific study of these cases? And we may foresee none except perhaps it come from human vivisection, which we neither desire nor will a righteous public sentiment permit.

We suspect that the real crux of the difficulty, the final bar in the half-conscious parts of the public mind preventing the admission of the cogency of the foregoing and other arguments not enumerated, lies in the fear of the psychologic purity of its own motives and character. Civilized humanity half feels that it can not trust its own religion and ethics which like a thin lava-cooled stratum lies over the volcanic brutality of fire, and the pent-up untamed fury of elemental barbarism beneath. The public consciousness distrusts itself, and fears if it should give away in this one evidently advisable procedure, the mountain itself would burst forth and again would come the antique savage pitilessness for the weak and the reign of brute force such as we see in Africa and in the animal world.

But the fear may be brushed aside. Surely civilization and law are more firmly based than that in our human life. We must trust ourselves and the future more than this, otherwise all progress is stopped, and we must settle down to an iron rule of routine and precedent. BAGEHOT's "cake of custom" is much better baked than our fear would imply. And, too, humanity is ruled to some degree by reason and kindly motives, not by determinism and mechanics alone. If we assent to the death of the hopelessly idiotic, we need not, and certainly shall not, proceed to the slaughter of the sick, weak, insane, etc., etc. The method of civilization is discrimination, and there is no doubt we have learned to discriminate in other things, why not then in this? In law, because we pronounce the death-penalty upon the cold-blooded murderer, do we therefore punish in the same way the kleptomaniac or the drunkard?

It goes without saying that the proposal thus to dispose of these poor creatures must be safeguarded with every preventive of abuse and error. The decision may be vetoed by a parent, and only advised by a commission of scientific men from the legal and medical professions, chosen by the highest executive officers, and carried out with every wise precaution dictated by humanity and religious feeling. But it must come about that all such considerations having been duly weighed and all proper precautions having *been established, the proper "medical treatment" of a* hopeless case of idiocy will be finally recognized as a lethal dose of some anesthetic.

THE OCULAR MANIFESTATIONS OF INTRA-CRANIAL TUMOR.

There can certainly be no difference of opinion with regard to the utility of ophthalmic examinations as an aid in the study of diseases of the nervous system. While not invariably conclusive, the information gained by this means often decides the diagnosis *and not rarely determines the treatment to be employed.* That the findings are not always unequivocal while lessening somewhat does not wholly neutralize their usefulness. So-called pathognomonic or infallible signs or symptoms are to be viewed with suspicion.

The views of competent authorities as to the significance of optic neuritis in relation to intracranial neoplasms have been widely divergent, some insisting that the phenomenon is of the greatest diagnostic and localizing value, while others have contended with equal positiveness that it is entirely unreliable in these directions. With a view to shedding additional light on this important question MARTIN (*Lancet*, July 10, 1897, p. 81) undertook an analysis of 600 cases of intracranial tumor derived from various sources.

As a result of this study it was found that in 513 cases in which the sex was stated, 353 (68.8 per cent.), occurred in males and 160 (31.2 per cent.), in females. The distribution of the new growths was as follows; cerebellum, 138; motor area, 120; frontal area, 61; pons and medulla, 45; parieto-occipital area, 37; basal ganglia, 36; centrum ovale, 30; temporosphenoidal area and multiple, each 28; pituitary, 26; general, 19; corpora quadrigemina, 15; corpus callosum, 13; crura, 5. The nature of the growths was as follows: Sarcoma, 126; glioma, 82; tuberculous, 72; cystic, 44; gumma, 36; gliosarcoma, 30; hydatids, 21; carcinoma, 11; other varieties, 179. A study of the chief situation of the headache in the cases in which this symptom was noted confirms the prevailing idea that this is of no significance in determining the position of the tumor. The number of cases in which tumors of the motor area and of the corpus callosum were unattended with headache is considered noteworthy, as well as the frequency of occipital headache in association with cerebellar tumor and of frontal headache in association with tumors of all kinds.

The results of the analysis as regards the frequency of optic neuritis are in accord with generally accepted statements. This manifestation is noted with such frequency in connection with tumors of the corpora quadrigemina that its absence may be considered sufficient to exclude this condition. Optic neuritis was found in all of five cases of tumor of the crura, but the number of cases is too small to justify definite conclusions. Tumors of the cerebellum and of the parieto-occipital area were attended each with optic neuritis in 89 per cent., of cases; optic atrophy was more common after the former than after the latter. Optic neuritis was comparatively uncommon in association with tumor of the corpus callosum and of the pons and medulla. It was commonly absent early in the course of tumors of the pons. According to the percentage, the order of frequency with which optic neuritis manifested itself in association with intracranial tumor was as follows: Corpora quadrigemina, crura, cerebellum, parieto-occipital area, frontal-area, general, basal ganglia, multiple, pons and medulla, temporo-sphenoidal, centrum ovale, pituitary, motor area, corpus callosum. According to the percentage of cases in which optic neuritis appeared late, or was absent, or unilateral, the order of frequency was as follows: Cerebellum, corpora quadrigemina, parieto-occipital, basal ganglia, frontal area, pituitary, crura, general, centrum ovale, multiple, temporo-sphenoidal, motor area, pons and medulla, corpus callosum.

Only fifty-five cases could be collected in which the optic neuritis was unilateral or more marked on one side than on the other and of these the disturbance was more marked on the side of the lesion in thirty-nine and more marked on the opposite side in sixteen.

A study of the relation between the nature of the tumor and the development of optic neuritis showed the latter to be absent as follows: Tuberculous, 36 per cent.; gliosarcoma, 27 per cent.; sarcoma, 25 per cent.; gumma, 22 per cent.; glioma, cystic and carcinoma, each 18 per cent.; hydatid, 14 per cent.

Only thirty cases could be studied with regard to the relation between intracranial tumors and strabismus. Internal strabismus was found on the same side as the tumor in 23 cases and on the opposite side in four; and external strabismus on the same side in two and on the opposite side in one.

The general results of this painstaking and careful study are summarized as follows: 1. Of all cases of intracranial tumor 68.8 per cent., occur among males; 2. The most common form of intracranial growth is sarcoma; gliomata and tuberculous tumors are of about equal frequency, but less common than sarcomata. 3. Headache is more likely to be absent in connection with tumors of the motor area and of the corpus callosum than in connection with tumors situated elsewhere. 4. The tumor is generally situated on the side on which internal strabismus is noted.

Only limited localizing value is conceded at present to optic neuritis; but the hope is expressed that improved methods of examination now in course of adoption will give it greater value in the future. When a difference in the degree of optic neuritis in each eye exists it is more than twice as probable that the tumor is on the side on which the neuritis is the more marked. It should further be borne in mind: 1. That optic neuritis is constantly present in association with tumors of the corpora quadrigemina. 2. That it is present in 89 per cent. of cases of cerebellar tumor and of tumor of the posterior part of the cerebrum. 3. That it is absent in nearly two-thirds of the cases of tumor of the pons and medulla and of the corpus callosum. 4. That it is least frequently met with in cases of tuberculous tumor and is most common in cases of glioma and cystic tumor.

X-RAY INJURIES.

The extended use of the X-rays in surgical diagnosis has also developed certain inconveniences that attend their use, and the facts reported have received a very large amount of attention from the medical profession and the public. In popular estimation the occasional evil effects have been somewhat exaggerated, possibly in some cases to the embarrassment of physicians who desired to utilize this valuable diagnostic means. Among physicians themselves there has been some difference of opinion, and views that are without scientific basis are sometimes expressed as to the nature and the mode of action of these rays. There is so much that is unknown in regard to them, and the room for speculation is so ample, that it is no wonder that this should be so, any more than that the most extravagant tales of their powers should be credited by the general public.

Dr. N. Stone Scott, consulting surgeon to the City Hospital, Cleveland, contributes to the *American X-Ray Journal* for August a discussion and review of all the reported instances of injuries from this cause that he has been able to collect, with the special purpose of proving or disproving the assertions of some who have held that the deeper seated organs could be thus affected. In order to do this and to obtain all the information possible as to these injuries and the best means to avoid them, he sent out circulars to all the leading operators with these rays, asking for particulars of X-ray injuries, including the kind of apparatus, length of spark, number of exposures, distance of the platinum from the part exposed, and the character of the injuries themselves. The answers received, in his opinion, cover some twenty thousand applications, and include thirty-one cases of injury, which are tabulated together with those he was able to obtain in the literature. In all he reports sixty-nine instances, including twenty-four collected by Dr. Gilchrist of Johns Hopkins Hospital, whose views as to the production of periostitis he wishes especially to combat.

The general result of his study is that the X-rays undoubtedly do produce a dermatitis under certain conditions, chief among which are the distance of the platinum terminal from the skin and the length of the application. In two cases dermatitis or depilation was produced when the platinum was eighteen inches from the body, and in one of these the dermatitis followed three not very long applications aggregating less than an hour and a half. In three others burning pains followed a single application of less than half an hour with the platinum terminal ranging from ten to twenty inches distance. It would appear, therefore, that while in most cases the skin is affected only by long continued or close applications, or both together, there are some cases where, through idiosyncrasy, short and distant ones will have the same result. Dr. Scott's dictum that the most susceptible would probably not be affected by an hour's exposure if the terminal is ten inches away, is hardly supported by his tables.

In six of the tabulated cases, deeper structures than the skin are described as being affected, all of which he discredits to the extent of doubting the agency of the X-rays. In one of these, however, the case of cystitis reported by Dr. Lynn Thomas in the *British Medical Journal* in March of this year, he admits that they may possibly have aggravated the irritation caused by the calculus and thus furnished the last straw that brought on the trouble. In two out of three cases of possible induction of periostitis he thinks a *post hoc* deduction was made, and that the disorder was merely a coincidence, not an effect. In regard to Dr. Gilchrist's case, he analyzes it and attempts to show that it has been misinterpreted and that the skiagraphic evidences depended upon for the diagnosis were due to unequal exposures. He has produced the same appearances in perfectly normal hands by shading the thinner parts during part of the exposure, and he claims that the same result can be due to the thickened skin. As an X-ray expert, Dr. Scott's opinion is worthy of consideration, and as regards this special case he offers some valid arguments against the conclusions that have been deduced from it. It would not seem impossible, however, when we take account of the depth to which the dermal structures are often implicated, the subsequent deep and obstinate ulcerations sometimes reaching the bone, etc., that underlying parts might also be sometimes involved. A tibial periostitis would certainly seem a possibility, and there are other localities almost equally liable. The objection to the other cases, that there have been many hundreds of examinations without the production of similar injuries, only proves their rarity, and is not an argument against their occasional occurrence. His paper is not conclusive as regards this involvement of deeper structures, which is still to be considered an open question.

Dr. Scott briefly reviews the theories that have been advanced to account for these lesions, and makes no pretense of adopting any one of them. Electricians and not physicians are the ones to solve this question and he only concludes that if they are not produced by these rays themselves, it must be by something that accompanies them as any substance permeable by them is no protection. The natural deduction from this, which he does not make, would be that the skin itself is not necessarily a protection to the underlying parts.

The practical conclusion from his study is that to prevent X-ray lesions, the exposures should be short, not exceeding one hour for a distance of ten inches from the terminal and should not be repeated until a sufficient time has elapsed to show that no bad effects are likely to be produced. If repeated short exposures are made, the slightest bad symptom should cause their discontinuance. To this might be added the more general and comprehensive requirement to make the distance as great and the time as short for each application as is possible for the purpose required. We have as yet had hardly more than eighteen months experience with the X-rays, and know too little of their nature and the possible modifications of their action by idiosyncrasies, etc., to formulate any positive rules for safety in their use. Dr. Scott's paper, notwithstanding a certain bias that it displays, is on the whole a valuable contribution.

MEDICINE AND LETTERS.

The *Lancet* quotes Dr. Osler as having said of the late Dr. Oliver Wendell Holmes, that he was the best example that has yet been afforded by history of the successful combination of the physician and the man of letters. The combination is rare for many reasons, some of which lie on the surface while others are more remote. The career of a medical practitioner is an arduous one, and except in a few favored cases leaves little leisure for the successful prosecution of literary pursuits. On the other hand, for the attainment of any high degree of literary excellence ample time for reading, study, thought, and in a general way for self-culture is usually indispensable. Again, the physician is immersed in studies and duties which do not lend themselves very readily to literary expression, and he is prevented by professional etiquette and by good taste from making free use of the incidents of ordinary life as pabulum for authorship. Where gifts for practice and gifts for literature have co-existed in the same individual, the tendency has always been for one or the other to swallow up all the individual's energies and to brook no rivalry. Readers of Hippocrates and Galen will probably agree that if these distinguished men had not elected to be great physicians, they would have been great writers, and a similar feeling comes over us now and again when purusing the lectures of Sir Thomas Watson. Much commoner has been the phenomenon of the born poet, essayist, or novelist taking to medicine by some untoward accident, failing miserably, and then later discovering his true *métier*. Such was the case of Goldsmith, of Smollett, and of Keats. Of high excellence in medicine and literature the following examples occur to us, viz., Sir Thomas Browne, Arbuthnot, Oliver Wendell Holmes and John Brown. A true born poet, a born essayist, a brilliant and kindly wit, Oliver Wendell Holmes deserves to live long in the memory and affection of mankind.

Though Dr. Holmes finally all but abandoned medicine for literature, his professional training and experiences continued to color notably his literary productions. In the natural felicitous use of medical terms and ideas, free from every trace of pedantry, he has no rival. What can be more delightful than the following passage which we select almost at random: "Saddle-leather is in some respects even preferable to sole-leather. The principal objection to it is of a financial character. But you may be sure that Bacon and Sydenham did not recommend it for nothing. One's hepar, or in vulgar language liver, a ponderous organ weighing three or four pounds, goes up and down like the dash of a churn in the midst of the other vital arrangements at every step of a trotting horse. The brains also are shaken up like coppers in a money-box. Riding is good for those that are born with a silver mounted bridle in their hand, and can ride as much and as often as they like without thinking all the time they hear that steady grinding sound as the horse's jaws triturate with calm lateral movement the bank-bills and promises to pay upon which it is notorious that the profligate animal in question feeds day and night."

"Oliver Wendell Holmes is the best known instance which the century affords that medicine and letters are not necessarily opposed, and that there is no inherent antagonism between the qualities which constitute a wise physician and an efficient anatomist and those of the poet, humorist and sage. We rejoice that it is so. In these days of all-absorbing science the claims of literature recede, perhaps rightly, but it will only be for a season. Literature is perennially interesting, perennially fruitful. We trust the members of our profession will always be its lovers and not rarely its successful cultivators."

THE BRITISH MEDICAL ASSOCIATION.

The meeting of the British Medical Association at Montreal, which began August 31 and continued until Friday, September 3, was a notable event for our Canadian *confrères*. The selection of the place of meeting of this body and of the British Association for the Advancement of Science in Canada this, the Queen's Jubilee year, is in a measure possibly an indication of the new imperialism that it is the present English policy to establish, and will undoubtedly have an influence to draw Canadian and British medical and scientific men more closely together. Science, however, does not recognize strict national boundaries, and the program as published contains a very large proportion of papers from invited guests from this side of the line—enough, it would almost appear, to make the occasion an international one for the Anglo-Saxon race in America and Great Britain. It is well that this is so, not that we have any desire to encroach upon the privileges of our Canadian brethren, but because there should come nothing but good from the closer association of medical men of the same race, however separated politically. It is to be hoped that the meeting has been such a success in every respect that it will be repeated at some not very distant year.

CORRESPONDENCE.

LETTER FROM SWITZERLAND.

On Asiatic Plague and Cholera Centers.

Eschenz, Canton Thurgau, Switzerland, Aug. 12, 1897.

To the Editor:—One phase—and by no means the least important—of the vexatious Oriental question is how best to meet the threatened invasion both of Europe and America by the allied forces of the two great Asiatic powers, *Plague* and *Cholera*.

"All is fair in love and war," thought Solomon, when reflecting on his own origin, and espionage is an honest trade, provided one avoids being caught, for knowledge of the enemy's habitat and home life is of paramount value whether warring against pestiferous microbes, the Saracens or other powers of darkness; hence I have thought that a few brief sketches of the principal strongholds and recruiting camps of plague and cholera by a spy in the service of Hygeia might interest the readers of the JOURNAL, who are fellow soldiers, serving with me in the same army, though detailed to other lines of duty.

Before proceeding, however, I wish to ask: Are we forever, in this perpetual struggle against foreign pestilence, to merely remain on the defensive, with pharisaic self-consciousness of superior cleanliness and quarantine blunderbusses pointed eastward? This policy is in perfect harmony with our manner of protecting our Christian brethren in the land of the dawn against the cruelties of Muslim fanaticism with palaver and resolutions of mild disapproval; but is it wise? Is it humane? Why not attack the enemy's armies on their own soil, sterilize their breeding grounds and root out the whole brood, thus once and forever putting an end to this costly warfare.?

During the month of Zil-Hijjah, which this year corresponds with our May, vast hordes of bacteria of various denominations assembled at their annual rendezvous, Mecca, where while planning the ensuing year's campaign, they indulge in unrestrained riot and feasting. Their doings are never reported and their victims are never counted; vultures and other carrion-eaters constituting the only efficient health board. Perhaps the greater number of pilgrims arrive by over-land routes, whereby no barrier to entering the Holy City is encountered. Those from India and the Persian Gulf region come by sea, and these, if the ship carry more than one hundred pilgrims, must undergo quarantine inspection at Kamaran, while those from the north, Egypt and Northern Africa are inspected at Tor. But who knows anything of Turkish quarantine knows it is only a sham, a piratical black-mailing device, and bold indeed must he be who would seriously attempt to hinder a pilgrim from being at Mount Arafat on the 9th, the eve of the Feast of the Sacrifice, when each pilgrim must with his own hand slaughter a sheep. Imagine the effect of such wholesale carnage and an hundred thousand or more putrefying carcasses? True enough, man and beast gorge themselves with mutton, but the blood and entrails alone will poison the air for miles around before consumed by Araby's scavengers. Until the sanitation of Mecca shall be backed up by European military there is no betterment to be hoped for. An utter disregard for human life marks Muslim rule, and nothing is be expected from the Turk—except promises.

Leaving Mecca, then, with a caravan of surviving pilgrims and a firm resolve not to return while Turkish dominion continues to sway the destinies of mankind, we traverse the desert eastward into Mesopotamia, strewing the wayside with corpses as we journey on. Probably one-half of those who set out on a pilgrimage to Mecca never return.

Mesopotamia is a favorite resort for both plague and cholera —indeed Davidson says in his "Geographical Pathology" (page 281) that from 1856 down to 1885 the former was never absent from the country, but from investigations which I made while United States Consul at Bagdad, I believe this to be an exaggeration. The severest epidemic of this century occurred in 1831, when about one hundred thousand persons, or two-thirds of the whole population, succumbed. The horror of the situation was increased by the flood, which the city walls and embankments were unable to keep out; and 7,000 houses fell in one night, burying the inhabitants under the crumbled brick walls and other debris. The last epidemic occurred in 1871, and held on in various localities for considerable time. It is not likely that Mesopotamia will escape this year—indeed the pestilence may be raging now and the outside world be none the wiser; for whether a high or low mortality is to be reported and what name is to be given the disease causing it, is determined by the governor and health inspector in council, or even at times dictated from Constantinople.

The Persian funeral caravans are a source of great danger as well as revenue to this region. Probably no less than eight thousand corpses pass annually through Bagdad to their final resting place at either Kathmein, Kerbelah or Nedjef, holy cities, of which the first named is close to Bagdad and the two others some distance beyond the Euphrates. This traffic had, to the financial detriment of mosques, mullahs and merchants, been forbidden for some three or four years, when in the spring of 1894 the prohibition was withdrawn, and during the next six months more than twelve thousand defunct immigrants, many of whom had been dead from two to three years, arrived, each caravan bringing an hundred or more, and as the coffins were quite open in the seams and leaky, the odor was perceptible for several miles to leeward. The carpet and rug trade which had been languishing now began to revive, each caravan bringing a goodly supply to barter for other commodities. The choicest of these rugs are very old and have been kept in the daily living rooms of the natives for a couple of generations, exposed to disease germs of all kinds, before they are sent by the funeral caravans to Bagdad, whence they are exported chiefly to the United States to adorn the parlors of our aristocracy; while *en route* they serve as couch for the muleteers, many of whom sicken and die. How many billions of living tubercle bacilli or diphtheria bacilli, not to speak of plague bacilli and other imps, may not lie concealed in the meshes of such a rug! Let the quarantine authorities take due notice thereof and govern themselves accordingly.

Mesopotamia, below Mosul (Nineveh), is a low flat country partly desert, partly swamp land, intersected by numerous half-filled-up remains of ancient canals, monuments of agricultural industry in former and happier days, when according to Herodotus it was the most fertile region on earth, wheat yielding a two to three hundred fold harvest. It is subject to frequent inundations followed by pandemics of malignant miasmatic fevers. In the spring of 1894 the Tigris rose twenty-six feet and bursting through its banks in numerous places the desert for miles around was soon converted into a huge inland sea, many places from twelve to fourteen feet deep, with only here and there an island marking the site of buried cities, but for which, looking from the walls of Bagdad, there was a clear horizon all around. This lasted about six weeks, and as the waters subsided a luxuriant vegetation sprang up soon again to dry and wither, except in the lowest spots where stagnant water at a temperature of 90 degrees or thereabouts, and rapid decomposition of both animal and vegetable matter gave off noxious vapors for some weeks longer. As it was reported that the fellahs (tillers of the soil) along the river bank were dying in great numbers, and usually after only twenty-four to thirty six hours' illness, I resolved on finding out the cause which, however, I already suspected, and armed with four ounces of quinin and two ounces each of calomel and Dover's powder I started down the river. The first hut I entered seemed deserted but for a couple of asses, a few sheep and a dozen of chickens in the filthy mud-walled enclosure, besides a million flies disporting around a dirty rag heap, kicking into which several sallow sickly-looking Arab heads popped out. On inquiry if they were sick the answer was in the affirmative. I then told them that I was a physician who had come to cure them, when they set up a terrible wail, lamenting their poverty and assuring me they had no money with which to pay me for my medicines. Evidently they took me for a highway robber or tax collector, which here amounts to about the same thing. But when I told them I would cure them "for Allah's sake" and did not want their money there was great rejoicing. I made each one swallow forty grains of quinin and twenty grains each of calomel and Dover's powder; and thus I went from **hovel** to hovel as long as my supply of drugs lasted. The their ment confirmed my diagnosis, congestive chill; for all got well in a couple of days, while others continued dying.

It is generally held here that great inundations are the precursors of the plague, but this is not always so. The Bedouin notion of the etiology of plague is this, that it is caused by eating the flesh in a more or less putrid state of deceased camels. That there may be a grain of truth in this the history of the epidemic of 1871 would seem to confirm, though it may of course be merely a coincidence that it broke out first in an Arab camp where such food had been consumed. What probably helps to spread pestilential diseases are the grave robberies, the clothes in which the corpse was buried being afterward worn by the robber or even sold in the bazar. For this and other reasons many bury their dead, even during epidemics, under the house in the cellar or sardab, where in summer the family also on account of the heat pass the day.

Bagdad viewed from a distance is a painter's dream, but from within a sanitarian's nightmare. A labyrinth of narrow crooked streets, concave from side to side, so that when it rains they are merely canals of soft slimy mud, into the middle of which one is constantly gliding while trying to move along by jumping from right bank to left, or again jostled up against the walls by the waterworks, donkeys with goat-skin sacks on their backs; again during the dry season one is being stifled and choked with dust composed of desiccated and finely powdered human and asinine ordure mixed with a goodly number of tubercle bacilli, as one cautiously steps along to avoid freshly deposited human excrements. Now enter with me a bazar where food (meat, bread, fruits and confectionary) is exposed for sale, beside children with purulent ophthalmia, and hungry, emaciated, vagrant dogs, reposing on ash heaps from the baker's oven, their bodies one mass of sores from snout to tip of tail (excellent material for a skin clinic), and too indolent or weak to even dispute with the crows the right to the sheep entrails, fish heads and other offal lying around all covered with flies (except during the hot season when most insects perish) that are alternately feasting on the pus exuding from between the children's eyelids, the living but denuded flesh of the dogs and the dainties we are to enjoy for dinner.

I will here remark, while thinking of it, that during the summer when there are no flies there is little or no ophthalmia; but in October when the flies revive an epidemic of sore eyes breaks out, especially among the children. Against this, I was with the utmost care and cleanliness unable to protect even my own child.

But continue with me the exploration we have begun. Let us enter a private dwelling of the opulent class, where, as the massive gate swings open, we find ourselves in a spacious court with orange trees and palms, on the branches of which thousands of birds give vent to their feelings in joyful song, while above in apartments furnished with barbaric splendor and iron-barred windows, recline on softly-cushioned divans, gorgeously attired women—often literally bedecked from head to toe with gold, diamonds, rubies and pearls—smoking the nargileh or hubble bubble, and prattling. But take a look into the kitchen (on the ground floor), where in a corner is a heap of rubbish, egg shells, bones, etc., and beneath a capacious pit, into which the slops are emptied through a hole in the floor; or inspect the privy, a hole in the floor (no privy seat) communicating with a cellar beneath, near which, and separated only by a thin brick wall, is the well that furnishes water for dish-washing, etc., and the sardab or underground cave in which the family spend the hot summer days; all of which, slop pit, privy pit, well and sardab, are each spring when the river is high filled with water, that percolates through the porous soil and, to the great joy of the people, takes along with it when receding the year's accumulation of filth—truly, a land where dirt and diamonds dwell peaceably together. Again come with me to the river bank and watch the water carriers scooping up the thirst-assuaging fluid (muddy and with a slightly brackish or saltpeter taste in spring; greenish, slimy, ammonaical in autumn) in some shallow, stagnant or eddying nook where fecal and urinary contamination is greatest, and stranded carcasses of camels, horses, sheep, buffaloes, dogs and cats perfume the surroundings, and may be you will call for whisky straight with your dinner. But our inspection is not ended till we have passed a night on the housetop, Bagdad's summer bed-chamber, with no roof but heaven's vault, no walls but the horizon, where fanned by the north wind, we recruit our daily strength in peaceful slumber, and as you gaze on the cloudless and richly illuminated expanse above, more brilliant here than anywhere else in the world, you will also understand old Father Abraham's astonishment when it was announced to him that his progeny should become as numerous as the stars and you will also understand why the Chaldeans took so readily to astronomy.

During the summer months no rain falls and the air is so dry that ink dries on the pen between the inkstand and the paper; when writing I found it necessary to dip the pen for every word and twice for a long one. The prevailing winds are from the northwest and though fiery hot imparting a sensation as if one were holding the face before the open door of a furnace, they are yet refreshing; but southwest winds are very disagreeable, one can hardly breathe, the air seems lacking oxygen and they are also known as the "sickly winds," the "breath of demons." The mean annual temperature ranges from 74 to 76 degrees, the highest observed in the shade being 128 degrees and the lowest 31 degrees. I have once seen it 116 degrees on the roof of my house at 2 o'clock in the morning. The temperature of the Tigris water in summer keeps also between 80 and 90 degrees. The following temperature table gives a fair average for dwelling houses on the river bank, where, however, it is considerably cooler in the summer than in the city further back:

Month.	Mean.	Max.	Min.	During ten years.	
				Max. Mean.	Min Mean.
January	54	68	32	59	50
February	57	74	36	60	53
March.	63	86	45	68	60
April	72	90	50	75	68
May	82	102	64	86	73
June	90	114	73	91	86
July	94	118	78	96	91
August	93	122	75	97	86
September	89	108	70	90	87
October.	80	97	50	83	77
November	66	84	37	71	62
December.	56	74	31	60	52
	75 5				

Mild winters are usually followed by comparatively cool summers and *vice versa.*

Along the Persian Gulf the mean annual temperature is higher (from 80 to 84 degrees at Bushire and Muscat), but the range rather less, the temperature rarely falling below 60 degrees or rising above 108 degrees; but on account of the humidity of the atmosphere the heat is much more oppressive. In my next I shall treat of prevailing diseases of Mesopotamia and also of the sanitary administration, especially during the cholera epidemic of 1893. JOHN C. SUNDBERG, M.D.

Health at School.

NEW ORLEANS, LA., Aug. 11, 1897.

To the Editor:—May I trouble you to give me a detailed statement in regard to Dr. Clement Dukes' "Health at School," referred to in the excellent editorial on swimming which appeared in the last JOURNAL? I should like to know where and by whom the work is published, the size and price. If you could refer me to other works bearing on the direction of physical training in schools I should be much obliged, as I have undertaken to do work of that kind and wish to prepare myself for it. Hoping that this may not entail too much labor I am, with best wishes for yourself and the JOURNAL,

Very truly yours, H. B. G., M.D.

ANSWER:—See small work on "Swimming" by Martin Corbett (All-England series), London, 1890; also volume on "Swimming" in Badminton Library, by Sinclair and Henry, published by Longmans, Green & Co., a book of 452 pages with bibliography, London, 1893. Dr. Lagrange's work on "Physiology of Bodily Exercise." Appleton's International Scientific Series, 1890, has much useful information. "Physical Culture a Necessity," (*Vide* JOURNAL, Vol. xvii, page 513, Oct. 3, 1891.) See also Badminton's *Magazine of Sports and Pastimes*, Longmans, Green & Co., London.

The Diazo-reaction Test.

MINNEAPOLIS, MINN., Aug. 6, 1897.

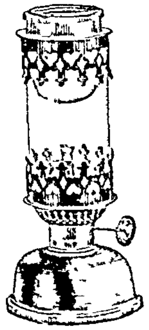
To the Editor:—Will you please inform me in what number of the JOURNAL, if any, I can find an accurate description of the method of making the "diazo-reaction" test in diagnosis of typhoid. If none has been published will you not have space for it? Very truly yours, F. A. KNIGHTS, M.D.

ANSWER:—*Vide* "The Diagnostic Value of Ehrlich's Diazo reaction," by Charles L. Greene, M.D., University of Minnesota, JOURNAL, Vol. xxii, p. 356, Feb. 24, 1894.

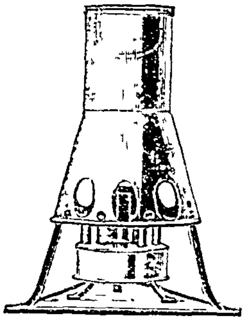
NEW INSTRUMENTS.

A NEW DISINFECTING AND DEODORIZING LAMP, AND A NEW FORMALIN DISINFECTOR.

We present illustrations of a new disinfecting and deodorizing lamp for household use, and a new formalin disinfector. In this disinfector the formalin is employed as pastils (Paraform) instead of the formerly used fluid form. The pastils are vaporized and the formalin given off in its gaseous form, *i.e.*, its most active form, as it thus penetrates everywhere in the room and the most resistant pathogenic forms are entirely destroyed. Other advantages are the even distribution of the gaseous formalin, the cheapness and simplicity of the apparatus and the fact that it does not injure fabrics, etc., thus making it unnecessary to remove furniture, ornaments, etc., from the room to be disinfected. To disinfect a medium sized room from 100 to 150 pastils are vaporized.



Deodorizing Lamp.



Formalin Disinfector.

The disinfecting and deodorizing lamp is constructed on the same principle as the formalin disinfector, but is smaller. The light need not be extinguished as the lamp burns out with perfect safety. Pathogenic organisms of moderate resisting powers may be effectually destroyed by the use of this lamp, foul odors removed and a preservative influence lasting two or three days given rooms containing food tending to decomposition. Alcohol or wood alcohol is used in both to vaporize the pastils, 2 ounces lasting from two to four hours in the lamp, according to the flame, while in the disinfector the reservoir is filled three-quarters full of alcohol, or one-half full if wood alcohol is used. These are supplied by Schering & Glatz, New York.

PUBLIC HEALTH.

Yellow Fever in Cuba.—A report from Havana, via Key West, Fla., dated August 21, states that the Marquis de Ahumada has been very ill but is now improving. Gen. Muncader, chief-of-staff for Capt.-Gen. Weyler, is also ill with the fever and for these reasons the latter officer has remained in Havana. The sanitary condition of affairs is supposed to be more alarming than the vague rumors admit.

Health of San Francisco.—The report of the Health Department shows 470 deaths for July, 1897, and 443 births, in an estimated population of 360,000. This makes the death rate for July 1.30 per thousand and 15.60 per annum. The principal causes of the July mortality were: Phthisis pulmonalis, 70; heart disease, 69; cancer, 36; violence, 33, and pneumonia 28 cases.

A Suspected Case of Yellow Fever.—According to the press reports the steamship *Finance* from Colon arrived at the port of New York August 21, and brought in a seaman who was taken ill three days before. The patient was removed to the Swinburne Island Hospital, and the second cabin passengers and the crew were transferred to Hoffman Island. The vessel was disinfected and allowed to proceed to her pier, where the cabin passengers were landed.

Destruction of Cargo of Grain by Mexican Board of Health.—The sale on shore of the cargo of grain on the American ship *Frank Rood*, stranded near Vera Cruz, was forbidden by the local health authorities, as the grain had been slightly wet. To prevent sickness from the decaying mass, the sea was allowed to wash it away, and the owners were paid $100 indemnity by authority of the National Board of Health.—*Boletin del Consejo S. de Salubridad*, June.

The Daily Water Supply of New York is 225,000,000 gallons. The new system is to add 65,000,000 gallons through the Fifth Avenue mains, and 20,000,000 by the others. The new aqueduct system is capable of producing 400,000,000 gallons should they ever be needed. New Yorkers seem to gloat over the assertion that the pumping costs Chicago four cents per thousand gallons, while the cost to New York for the same volume is only two and a half cents. Happy is Chicago to be mentioned in the same breath.

Joyful News for School Children.—In Marpman's bacteriologic institute at Leipzig, the ink bacillus has been discovered and duly named. Out of fifty-seven different kinds of school inks examined, most of them made with nutgalls, the greater number contained bacteria. School inks colored with an anilin dye, even though the bottle had only just been opened, contained the micro organisms already mentioned, and the number of bacilli was the greater the longer the ink had been exposed to the air. From such an anilin ink, which had been in an open inkstand for three months, a specific bacillus was isolated and mice were inoculated with it. After four days they died of blood-poisoning.

The Most Populous Block in New York according to the Federation of Churches and Christian Workers is on the West Side, and is bounded by Amsterdam and West End Avenues and 61st and 62d Streets. The population count is 3,580. Squalor reigns supreme. Irish, Germans, Italians and Austrians furnish the material for racial wars. The Hebrew is the only absentee and the Austrian butchers constitute the only placid element. The "head of the family" wages averages $12.50 per week. Three tiny, narrow rooms are the most a family can expect, and for these a rent of $10 to $12. The 3,580 people live in 2,639 rooms, the kitchen always the "living room," and less than twelve hundred of these have an outside window. The tenements are all patterned alike, one long row of dull red brick structures that, sav [illegible] d stoop, as well be factories. The block has an environment all its own. Despite the crowding of the region, many lots to the north along West End Avenue are vacant, the rocks that in places are miniature cliffs have not been blasted away, and there are still some remnants of "Shantytown" overlooking the railroad track. Heaps of lumber and rods of sewer pipe extend in every direction. Strange to say these dwellers upon the steep hill care but little for the partition bath tubs of ingenius owners, not as much perhaps as for the marble palaces on Fifth Avenue. A proposed North River bridge may disperse the tramps from the railroad and New York may yet have an opportunity to weep for those sanitary sins, which to her seem the most precious.

Health in New York.—The report of the State Board of Health for July shows a mortality of 11,235, greater than that of June by 2,200, but 1,400 less than that of July, 1896. Compared with June, 1897, deaths were as follows: From diarrheal diseases, 1,900 more; from diseases of the digestive organs, 300 more; from accidents and violence, 200 more; indefinite causes, 200 more. Diphtheria decreased by 100 in mortality; scarlet fever and measles somewhat; and respiratory diseases by 250, while typhoid fever moderately increased. The death rate from all causes was 20.50 against 16.75 in June, 45.5 per cent. of the deaths occurring under five years of age, against 31.5 per cent. last month.

The Percentage of Diseased Cows in the City Limits of New York is put down at 16.3. The board has supervision limits over 2,700 cows. The milk from 550 of these is consumed by the owners, and the rest sold. Of these cows 1,139 were examined by experts and 186 were condemned as diseased, after being subjected to the tuberculin test. The official diagnosis was confirmed in each case at the autopsy. The tuberculin used in the tests was produced by Koch's method at the board's laboratories. President Wilson says that he is satisfied, faom the work of the officers having supervision of the city's milk supply, that milk will continue tainted to a greater or less degree until the authorities of Connecticut, New Jersey, Pennsylvania and Massachusetts adopt as rigid laws as are enforced by the New York Health Board. He meekly intimates to taxpayers that more ample appropriations would be gratefully received.

Alcohol at Rouen.—The liquor dealers sell more to families at home than across the counter. To study better this frightful state of affairs, Dr. Brunon took service as a waiter in one of the liquor shops, which number fifty to each one hundred houses in town. He relates that it is a frequent practice for a family to order a liter of alcohol, which it was his duty to deliver early in the morning. A large soup tureen was filled with slices of bread, boiling coffee poured over them, and the soup seasoned with half the alcohol. This is the morning meal for the whole family, including the children. If there are more than four in the family, the entire liter is emptied into the soup. They are not hungry afterward during the day, but the thirst is inextinguishable till evening. There are 4,600,000 liters of alcohol consumed annually by a population of 112,352 (census of 1891).—*Gaz. Méd. de Liège*, July 22.

Oysters.—"A recent official medical report, published in the London *Lancet*, quotes with approval the words of Prof. Conn that the public health is placed in jeopardy when oyster dealers, for the sake of producing plumpness, place oysters in the mouths of fresh-water creeks in close proximity to sewers."—*New York Med. Record*. There should be a law prohibiting this practice, but such a law would necessarily be enforced with difficulty. Dr. Klein has made some very interesting examinations of oysters, concerning the possibilities of infection from sewage, to which the London *Lancet* of December 5, devotes considerable attention. While these examinations may prove impurity and hazard, it is difficult to state the precise nature of the specific hazard. It is unfortunately true that the typhoid bacillus has been found by Dr. Klein in one instance. Another very interesting paper on "Oyster Culture and Disease," is to be found in the *Brit. Med. Jour.* of Nov. 20, 1896. The investigations of Dr. Cartwright Wood, concerning typhoid fever germs in oysters, while they confirm the opinion of Dr. Klein that shell-fish can carry infection after exposure in polluted salt water, do not consider the possibilities of infection arising in the oyster after it has been removed from salt water. The oyster is undoubtedly capable of absorbing poisons, not only through the medium of water, but also by means of exposures to foul air. We are well aware how rapidly milk absorbs odors, whether of a poisonous nature or not, and this property oysters also possess. A putrid infection is readily induced in structures so favorable for infection as the oyster or clam. Atmosphere loaded with disease germs imparts a contaminating influence to jellies, vegetables, meat, and bread, as well as to milk, fish and oysters. A wholesome storeroom is the suggestion, not the rule.

The Sanitary Regulation of the Sleeping Car.—The Louisiana State Board of Health has recently investigated the subject of the sanitary defect in our sleeping-car systems, and the following resolutions have been adopted: Be it

Resolved, That every sleeping-car entering the city shall, on its arrival, be thoroughly cleaned and disinfected, under the surveillance of our sanitary inspectors, as follows: 1. The towels, bed clothes, etc., to be submitted to a vigorous disinfection by ebullition in water for an hour, or sterilized in an autoclave or steam oven. 2. The closets and cuspidors (these should be of china-ware, not metallic) to be washed out with antiseptic liquids and always provided with a supply of such solution. 3. The car proper to be disinfected by means of formalin. This agent positively kills or destroys the germs of tuberculosis, diphtheria and smallpox in a few minutes. It causes no appreciable injury to the woodwork, upholstery and carpets. The method of applying it is very simple. It can be applied in the form of fumes or by a special apparatus. It applies to mattresses and pillows and cushions, as it possesses most penetrating properties. The disinfecting process can be carried out quickly and at little expense."

The subject of car sanitation is one that appeals to the large majority of our population on account of its possibilities in regard to transmission of contagious diseases. That such diseases may be transmitted in this manner is admitted by all sanitarians, and the danger of contracting diphtheria, syphilis, eruptive fevers, etc., from lack of cleanliness in sleeping-coaches, is not a remote possibility, but an actual reality. The transmission of tubercular disease in this manner has been disputed, but there is no doubt but that in certain depressed conditions of the system, when the ordinary forces with which nature surrounds us to guard against the encroachment of infectious diseases have been weakened, that the inhalation of dust containing tubercular matter is wrought with serious danger. The subject of the sanitary regulation of sleeping-coaches is one of the utmost importance, and these regulations should be made universal. The adoption of proper resolutions by the Louisiana State Board of Health is of importance not only locally, but it may be the entering wedge for the establishment of similar laws in other parts of the United States. If such laws existed in New York, Ohio, Pennsylvania and Illinois as well as in Louisiana, it would be a fairly satisfactory guarantee that travel east of the Mississippi had been deprived of its worst sanitary dangers. Such a movement would soon be followed by similar regulations by other States, so that finally traveling in the United States could be undertaken without the danger of contracting diseases to which we are now exposed by the unsanitary condition of the sleeping-car.

Report of a Study-travel to the Tuberculous Establishments of Germany and Switzerland.—Edv. Kaurin (Director), Molde, Norway, who has been nominated for the directorship of the first popular hospital for tuberculosis in Norway, used last autumn a traveling stipend to visit the tuberculous establishment of Falkenstein, the best known of Germany, and whose director is the Privy Councilor Dettweiler. He gives a detailed description of this institution, which is situated most picturesquely in the mountains of the Taunus, 400 meters above the sea level. The establishment is very comfortably appointed, and is in every respect a model institution, having spacious rooms for the patients and several pavilions in the beautiful park surrounding it. At a short distance is the popular sanitarium of Ruppertshain, a very well organized place which was started about a year ago, and which is much frequented by patients of small means; they enjoy the best attendance for from two marks fifty pfennigs to five marks a day. The usual duration of the treatment is three months. In the two houses the treatment is hygieno-dietetic, Dettweiler's method according to Brehmer, which is based principally on the dwelling of the patients in the open air, in the winter as well as the summer, in large rooms open on one side, and on the hardening of the skin and a very abundant nourishment. Few medicaments are employed and on the whole there is only a symptomatic treatment. Results are quite satisfactory and there are 24 per cent. of cures. The author emphasizes the fact, which is proved by the statistics of the towns of Falkenstein and Görbersdorf, that there is no reason to fear that such establishments may transmit the contagion to the inhabitants of the surrounding country. The contrary seems to be proved, as the frequency of tuberculosis diminishes in the regions, the establishments in question acting outside as educators with regard to measures to be taken against infection. In Switzerland the author visited Heiligenschwendig near Thoun, which is the first in date of the popular sanatoriums of Switzerland. It is situated in the Canton of Berne, 1,100 meters above the level of the sea. This establishment has not been long in activity and is calculated to receive about fifty patients, but they have now begun to enlarge it so there will be room for 120 patients. The author also describes the Baselian therapeutic establishment at Davos, which was not yet finished. It is a sanatorium founded by the city of Basel for its impecunious sick. There is also the well-known sanatorium of Dr. Turban, and the Kurhaus of Davos. He mentions pensions, established in Davos, for young people with the beginning of phthisis or a tubercular disposition; they can there, under the eye of a physician, go through a whole course of study, all the time taking good care of their health. He also speaks in detail of the climate of Davos. The sojourn in this locality seems to be contraindicated only for high graded anemia and neurasthenia or pronounced cardiac weakness. The author then passes to the detailed description of the institutions existing at Görbersdorf, that is, the old establishment of Brehmer, the sanatorium of Dr. Römpler, the establishment of Dr. Weicker and his hospital for impecunious tuberculous patients. He shows what importance this school of Görbersdorf attaches to life in the open air, in large well-protected parks with numerous avenues, whose slopes are various. In the environs of Berlin the author visited the popular sanatoriums of Grabow, Malchow and Blankenfeldt. In the first of these localities the tuberculous are installed in huts *à la* Döckert, which have been put at the disposition of the establishment by the Red Cross, and built in a large pine wood. The two other establishments are built in the irrigation fields of the city of Berlin; their situation is in consequence not excessively advantageous, but they were not originally meant for receiving tuberculous patients. Both, however, considering the short time of their activity, have furnished good results of the hygieno-dietetic method there applied. Everywhere in Germany and Switzerland people were most earnestly interested in the question of tuberculosis. The struggle against this disease is engaged in, in both countries, with uncommon ardor and a final victory is confidently hoped for.—*N. Mag. f. Laeger.*, No. 2, 1897.

The National Conference of State Boards of Health was held at Nashville, Tenn., August 18 and 19 and the following questions discussed:

"Should the tuberculous insane be isolated from inmates in our asylums, and accommodations provided for them in separate and detached buildings?" "What municipal ordinances shall Boards of Health advise for restriction of tuberculosis?" "What attitude are the State Boards of Health prepared to take regarding the new law for general inspection of dairy cattle, and what are the details of any practical scheme for inspecting herds supplying public milk, dairy produce, for dealing with animals which react to the tuberculosis test?" "To what extent should State Boards of Health be expected to furnish a diagnosis of contagious diseases within their jurisdiction?" "How far should mandatory measures go in dealing with measles, whooping-cough, leprosy and tuberculosis?" "Relations of National and State Quarantine?" "Should Boards of Health tolerate the feeding of hogs with offal from slaughter houses or meat from knacker's yards?" "Should the county jails and prisons of the different States be placed under the sanitary supervision of their respective State Boards of Health, which shall have them inspected regularly at stated intervals by a health officer appointed by them or under their control?"

In June a conference of baggage agents, health officers and funeral directors was held at Cleveland, Ohio. A committee representing this conference made a report "recommending changes and amendments in the present methods of embalming, disinfecting and transporting of dead bodies." We give a synopsis of the regulations recommended in this report, which with a few amendments was adopted:

1. The transportation of bodies dead of smallpox, Asiatic cholera, yellow fever, typhoid fever or bubonic plague is absolutely prohibited.
2. The bodies of those who have died of diphtheria, scarlet fever, glanders, anthrax or leprosy, to be accepted for transportation only when prepared for shipment by being thoroughly disinfected by arterial and cavity injection, disinfecting and stopping of all orifices with absorbent cotton and washing the body with disinfectant.
3. Bodies of those dead of typhoid, puerperal fevers, erysipelas, syphilis or other dangerous, communicable diseases may be prepared for shipment by filling cavities with improved disinfectant, washing the exterior of the body and stopping all orifices with absorbent cotton. In cases of contagious, infectious or communicable diseases the body must not be accompanied by persons or articles which have been exposed to the infection.

The Secretary was instructed to report this action to the executive officers of each State and Provincial Board of Health and request such action as they saw fit. Dr. Benjamin Lee of Pennsylvania, was chosen president; Dr. Formento of New Orleans, vice-president; Dr. Hurty of Indiana, secretary; Dr. Pelletere of Quebec, treasurer. The meeting for 1898 will be held at Detroit, Mich.

Alleged Unwholesome Meat in Germany.—According to the *Consular Reports* of February, a report to the United States Government from Cologne sets forth that the Germans are not satisfied with the kind of examination to which meat products for export are subjected before they leave our shores. The agitation appears to be conducted in the interest of the German agriculturalist. At a recent meeting of the agricultural association of the district of Cologne the subject of adulterating German sausages with American diseased beef was discussed. According to the Cologne *Gazette*, one speaker, in discussing this question, drew special attention to the fact that beef was examined for maggots in Germany but not so in America. Since, in the former country (Germany), sausages were more adulterated with American beef that was infested with maggots than with potato meal, the law in force in Germany against dishonest competition should also be applied in the case of sausages, which would require the marking of the goods as to whether they were of German or foreign origin and had been officially examined or not. Another spea[illegible]r remarked that it made an immense differ[illegible] we[illegible] the German people whether home or fo[illegible] therefore deemed it necessary that [illegible] d in the preparation of sausage be given. A chemist present, in speaking on the same subject, said that American beef was not so profusely infested with maggots but that it came to Germany prepared with borax in an astonishing manner. On the exterior of the meat there was a complete crust of borax and the meat was actually pickled with borax. If sausages contained meat prepared in this way and were offered for sale it was clearly a fraud in the sale of foodstuffs. But this importation had only commenced with them as well as the discovery of its harmful effects.

SOCIETY NEWS.

The American Academy of Railway Surgeons will meet in Chicago Oct. 6, 7 and 8, 1897.

The Eighth Italian Congress of Internal Medicine is to be held at Naples in October. De Renzi and Marchiafava will present the subject of "Leukemia and Pseudoleukemia;" Cardarelli and Silva, "Cardiac Neuroses"; Fenoglio and Massalongo, "Chronic Arthropathy," while Devoto and Ferrannino will review the year's progress.

The Seventh Morwegian Medical Congress was held at Trondhjelm, August 3 to 5. Among the communications of more than local interest, we note that addresses were delivered by P. Aaser, president of the Norwegian Medical Association on "The Position of the Physician in regard to Life Insurance Companies;" "Psychiatric Diagnosis in Theory and Practice," H. Dedichen; "Medical Secrecy," Foerden; "Retention of Urine," K. Jervell; and "Heredity," E. Storen. Professor Laache is the official delegate from Norway to the Congress at Moscow.

Third Italian Medical Congress, Novi, June, (Ligurian). Prof. E. Maragliano delivered an address on the "Cure of Nephritis," which he bases on the principle of regulating the proportions between the nitrogen introduced and the nitrogen eliminated. This therapeutic indication is sufficient to cure acute cases and prolong life in chronic. He concluded with an urgent appeal to all physicians to follow the new scientific paths and seek to discover disease in its latent and early stages instead of waiting until it is so difficult to control. G. Ingianni reported the results of experimental research in suture of the vas deferens on dogs, inserting absorbable substances to facilitate the suture and hold the walls of the canals apart. In all his experiments, the two stumps united perfectly, but the canal remained impervious, which is contrary to the general assumption. E. Terrile of Genoa, described the pathogenesis and therapeutics of tuberculous polyserositis which he ascribes to toxins in the blood in the course of a latent or manifest tuberculous infection. The two cases he described were cured with Maragliano's serum. Prof. C. Poli of Genoa, referring to the operative cure of endocranial complications of purulent otitis media, described several cases in which the operation gave issue to pus from the lateral sinus, although no previous symptom had indicated this complication. As this represents the first stage of endocranial diffusion, he urges the necessity of being on the lookout for it and of investigating the condition of the ducts of the sinus in resection of the mastoid. Prof. L. Levi reported the fine results obtained by the use of endovenous injections of corrosive sublimate in the cure of the localizations of the gonorrheal virus in the articulations. The fever disappeared at once and also the pains in the joints. It is the first time that this treatment has been attempted. He concluded by calling attention to the serious complications of gonorrhea, which is too often neglected as of little consequence. Prof. L. M. Bossi suggested among other new obstetric regulations that the sanitary authority should be informed at once whenever abnormal conditions were found on combined vaginal examination, at the puerperium. Bajardi presented an improved tracheotome, which enables the operation to be performed in two parts, and without assistance or hemorrhage. It is a three-quarters curve and is introduced into the trachea guided by a hook previously inserted. L. Macaggi presented a female catheter, with a double flow, to secure permanent antiseptic irrigation in cases of vesico-vaginal fistula, which he considers of great importance. It is held in place by the sphincter. Prof. E. Sacchi reported favorable results in operations on the deferens, for prostatism in eighteen cases. L. Devoto stated that iron alone is not sufficient to cure chlorotic anemia, but that equal stress must be laid upon repose, suppression of liquids, use of mixed alimentation,-disinfection of the stomach and intestines, and administration of sulphur with the iron medication. S. Personali mentioned that erythromelalgia does not represent, in all cases, a distinct disease, an autonomous neurosis, but that it often coincides with the repullulation of syphilitic symptoms, and is therefore a significant symptom. Sacchi presented a patient whose larynx had been extirpated *in toto* twenty months before, and replaced with an artificial organ. He can speak correctly and be understood even at a distance. Deamicis described a case of incoercible vomiting in pregnancy finally controled by chloronarcosis. Gasparini asserted that ulcerations of the nasal or oral mucosa are the cause of clonic facial spasms, and when they are cured, especially with anodic electrolysis, the spasms cease. The fine results obtained in infantile myxedema with thyroid extracts were confirmed again, and various deformity apparatuses for the jaws, etc., were exhibited, Giuria signaling the importance of applying such an apparatus at once before cicatrization has produced deformity. Prof. Morselli proposed a modification of the Sanitary Code to place foreign physicians practicing in Italy, especially in the Riviera, on the same footing as Italian physicians practicing in foreign countries, and not allow them so many privileges as at present. E. Roncagliolo proclaimed the efficacy of guaiac *per via epidermica* in the cure of erysipelas of the face. It has been in use for three years at the Genoa clinic, and has been found effective in arresting the disease in its early stages, and curing it when more advanced. The complications are rare. He believes that the guaiac neutralizes the toxic substances in the circulation by its direct or indirect action on the cellular protoplasm. —*Gaz. degli Osp. e delle Clin.*, July 18.

NECROLOGY.

M. A. Muniz, M.D., Lima, Peru, aged 36 years, Professor Med. Physics and Hygiene; Superintendent of National Insane Asylum, and Chairman of the National Board of Health. *La Cronica Medica*, June 30, is devoted to a review of his brief, brilliant career, and his indefatigable labors in general for the progress and enlightenment of his country. His articles on "Leprosy" and the "Demographic Statistics of Peru" won him membership in the French Société d'Hygiène. Those who attended the First Pan-American Congress at Washington may remember his interesting address on the Incas and his collection of Inca skulls.

Kauffman, M.D., Bellevue Hospital Medical College, New York, 1867, Chambersburg, Pa., August 13, aged 56 years.——George Y. Lehr, M.D., Jefferson Medical College, 1863, Philadelphia, Pa., August 18, from carcinoma of the stomach, recurrent after an operation one year previous. He was born in Gratz, Dauphin Co., Pa., 1847.——D. F. Burner, M.D., Woodstock, Va., August 23.——J. B. Clark, M.D., Economy, Ind., August 21, aged 45 years.——J. R. Hipple, M.D., Waldo, Ohio, August 18, aged 70 years.——E. C. Putnam, M.D., Alma, Neb., August 9, aged 44 years.——Wm. H. Slevin, M.D., Toledo, Ohio, August 18, aged 30 years.——Dr. R. de B. Martins Pereira, Professor in the Lisbon School of Medicine.——Dr. Victor Mayer, Professor of Chemistry in the University of Heidelberg, author of a "Manual of Organic Chemistry" and of many important contributions to organic chemistry, aged 48.——Dr. Benjamin Clémenceau, father of the political leader of that name, aged 87. ——Dr. C. J. Ask, Professor of Surgery in the Swedish University of Lund.——Dr. Joseph Kovács, Professor of Surgery in the University of Buda-Pesth, aged 65.——Dr. Cesareo Magdalena, Assistant Professor in the Madrid Bacteriological Institute.——Dr. B. F. Sherman, Dean of the Medical Society of the State of New York, of which he was President in 1884, aged 80.——Dr. F. H. James, a notable connoisseur and collector, and one of the best authorities on numismatics in the United States, aged 72.——Dr. T. Bogomoloff, Professor of Medical Chemistry in the University of Charkoff, aged 55.——Dr. Kremnitz, Physician to the Crown Prince of Roumania.

MISCELLANY.

A Roentgen Ray Institute in Berlin has been established under the supervision of Professor Grunmach, chiefly for diagnostic purposes.

A Scientific Latin-American Congress has been organized by the Societa Cientifica Argentina to celebrate its twenty-fifth anniversary. It will be held at Buenos Ayres, April 10 to 13, 1898, and is to be international. The medical sciences are to form an important section.

Correction.—In "The 'Schott Treatment' of Cardiac Diseases," by Dr. Camac (*vide* JOURNAL, August 28) the amount of sodium bicarbonate in bath No. 6 (p. 412) should be two pounds instead of one, which made an excess of HCl, injurious to the patient and the tub. In the discussion following the reading of the paper, the remarks of Dr. Smith of New York should be accorded to Dr. J. J. Morrissey of New York.

The Gold Harben Medal presented to Dr. v. Pettenkofer of Munich, the famous German hygienist, by the British Institute for Public Health, was first awarded in 1895, when it was presented to Sir J. Simon, at the time at the head of the English sanitary service.

Back Number Wanted.—The issue of the JOURNAL for July 3, 1897 has been entirely exhausted and in order to supply the demand for copies made by those desiring to fill their sets for binding, the JOURNAL will pay 10 cents a copy for the return of this number.

Fauvelle Prize Awarded to Prof. Ramon y Cajal of Madrid.—The Anthropologic Society of Paris has bestowed this prize of 1,200 francs in recognition of the valuable researches of Prof. Ramon y-Cajal in the physiology of the nervous system. He had not contributed any special work to the society.—*Arch. de la Policlinica*, June.

New Sign of Early Tabes.—In a patient with tabes it is often possible to flex the leg at the hip without bending the knee until the toe almost touches the ear, without producing the sense of painful tension in the popliteal space so speedily felt by one in health. This is not only an interesting feature of advanced cases, but is a valuable early diagnostic sign.—*Health*, August 14.

Toxin in the Urine of Cancer Subjects.—Castelli has found in the urine of patients with cancer and cachexia a toxic element of extreme virulence. Injected into animals it produces the clinical picture of the characteristics of the blood in cancer, determining a hematolytic or inhibitory effect on the hematopoiesis.—*Archivos de la Policlinica.*

Surgery of the Stomach.—Carle and Fantini conclude from the results of eighty-four operations on the stomach, that many of the so-called neuroses of the stomach rest upon anatomic foundations, and that a simple operation to remove the cause would relieve them. They found in every case that excessive hypersecretion of hydrochloric acid ceased as soon as the obstacle that was causing stagnation was removed.—*Gaz. d. Osp. e d. Clin.*, July 1.

Sero-therapy and Surgical Tuberculosis.—D. Dasara has been very successful with Maragliano's serum supplementing surgical intervention in a case of tuberculosis of the bones and joints, described in the *Gaz. de Osp. e d. Clin.*, 34. Similarly favorable results are reported by Beccaria (in No. 78) in cases of cervical and submaxillary adenitis accompanied by kerato-conjunctivitis, with tuberculous antecedents.

Wound into the Spleen.—The deep wound in the upper lateral left hypochondrium was made with a shoemaker's knife and extended into the spleen. The hemorrhage was diffuse, characteristic and alarming, but was controlled and the wound healed by first intention in a very brief time. Treatment: Antiseptic irrigation and tampon of gauze tightly packed into the wound, with compressing bandage; the incision in the skin enlarged to allow of closer packing.—*Cronica Medica*, June 15.

Hypertrophied Prostate Thirty-five Days After Double Castration.—The connective tissue was found hypertrophied to such an extent that the gland tissue was either completely atrophied or transformed into small cysts. The prostate was as large as a mandarin, hard, with a few soft spots when patient was first seen. Irrigation of the bladder was ordered for the accompanying vesical catarrh, and bilateral castration performed. The wound healed well, but the patient sank and died in thirty-five days. In such a case castration would obviously fail to relieve.—*Cbl. f. Chir.*, July 24, from *B. de la Soc. Anat. de Paris.*

Many Americans Attend.—Many members of the AMERICAN MEDICAL ASSOCIATION were present at the meeting of the British Medical Association at Montreal. Among the Americans present were the following: H. O. Marcy and F. W. Coles, Boston; Henry D. Holton, Vermont; T. D. Crothers, Conn.; W. W. Keen, J. B. Roberts and Edward Jackson, Philadelphia; S. C. Busey, F. B. Loring, Z. T. Sowers and D. Morgan, Washington, D. C.; Howard A. Kelly, Wm. Osler and R. W. Johnson, Baltimore, Md.; T. W. Miller, J. H. Hollister, E. F. Ingals, N. S. Davis, Jr., J. N. Hyde, R. D. MacArthur, W. E. Quine, A. R. Reynolds, D. A. K. Steele, F. Henrotin, John B. Hamilton, and others, Chicago; Frank P. Foster, G. F. Shrady, J. R. Goffe, R. W. Wilcox, A. R. Robinson, G. H. Fox, L. E. Holt, W. B. Noyes, A. Jacobi, F. S. Dennis, J. H. Fruitnight and S. J. Meltzer, New York City; P. S. Conner, Joseph Ransohoff and J. T. Whittaker, Cincinnati.

New German Law on Inebriety.—In the new code, the sixth paragraph, which will come into operation in Germany in 1900, enacts compulsory treatment of habitual drunkards. Among the persons liable to be interdicted, the interdiction involving being placed under a curator, who will be empowered to place the individual anywhere for treatment until discharged from curatorship by the court, inebriates are specifically mentioned. The exact description is, "he who, in consequence of inebriety, can not provide for his affairs, or brings himself or his family into the danger of need, or endangers the safety of others." This measure was first advocated in 1863, at a meeting at Hanover, presided over by Judge Naumann of Hameln.—*British Medical Journal*, August 7.

Prescription Defined.—According to the *Century* Dictionary and other recognized authorities, the word "prescription" is defined to mean "in medicine, a statement usually written of the medicine or remedies to be used by a patient and the manner of using them." So says the appellate court of Indiana in the case of Caldwell v. State, where it holds that the following writing: "B. W. Tilford, druggist, Martinsville, Ind., R. Spt. frumenti, qt. 1. For medical use. Date, Nov. 10, 1895. B. W. Tilford, M.D.," is not a prescription within the meaning of a statute prohibiting the sale of liquor on Sunday, except on a prescription therefor. It criticises the foregoing, and holds it defective as a prescription, for not being addressed to anyone, in not containing the name of the patient to whom the liquor was to be sold, nor the manner of its use. It further intimates that a prescription might be sufficient to inform the druggist of the goods desired, and in that sense, according to the United States Dispensatory, and not be sufficient to comply with the requirements of such a statute as that stated.

Censures Disclosures.—According to the record in the case of Loudoun v. Eighth Ave. Ry. Co., the appellate division of the supreme court of New York says, it would appear that there had been a disclosure by one of the medical witnesses for the defense of facts which he had obtained as the physician of the plaintiff. This, it continues, was done regularly and [illegible] ically, was a flagrant violation of the duty which he owed to his patient, and a contempt of the law which prohibits such disclosures. Under these circumstances, the court declares, the counsel was justified in calling the attention of the jury to the fact of this violation of law, of this failure of appreciation of the duties of a professional man to his patient, and of the flagrant abuse of the position which he occupied. It adds that it can not be said that any too severe language was used in criticising the conduct of a physician who would thus betray his patient. This physician had been guilty of the grossest violation of his duty, and was open to the severest criticism and condemnation.

"Sometimes" Evidence Inadmissible.—The appellate division of the supreme court of New York reversed a judgment for the plaintiff, and ordered a new trial, in the personal injury case of Blate v. Third Avenue Railroad Company, on account of a physician having been permitted to testify as to what "sometimes" happens as the consequence of a certain condition of things. It was not even an opinion of the physician as to the future condition of the plaintiff, or what would likely, or even possibly, happen to him as the result of the injury, that was elicited. But he was called to testify as to what sometimes results from such a condition as the plaintiff was found to be in, and that testimony was allowed to go to the jury under a complaint which alleged the permanency of the injury, and where the jury were instructed to allow damages for the injury that would follow from the condition in the future. This, the court holds, was error by which it was reasonably certain the jury were influenced to the disadvantage of the defendant, their verdict against the latter being quite large.

The Wire Saw.—Professor del Greco has been using L. Gigli's wire saw in his clinic for three years, and has gradually extended its use from simple resections of the ribs, until it includes all bone sections except those of the skull, and he proclaims its advantages in unqualified terms. It fits around the bones, and saws them accurately and delicately in any shape desired, never leaving a scrap unsawed, while it is yet strong enough for the hardest bones. It saws the soft parts also as evenly as a knife, and can thus be used alone for amputations, etc.; but its value is best shown in operations on the foot, which can be performed with extreme rapidity, with the foot in any desired position, and in any direction; the cut is as smooth and even as if soft parts and bones had both been cut with a knife at one stroke. It is also extremely effective in obstetric work. The inventor claims that it should take its place along with the elementary instruments, knife, scissors, needle, etc., in every surgeon's case. Bardenheuer recently mentioned its advantages in resection of the os ilei. It is made by Hartel of Breslau, on an entirely new principle, from a steel wire serrated on all sides, and can saw in any direction.—*Cbl. f. Chir.*, July 24.

Ballottement of the Bladder as a Test for Calculi.—W. M. Glagolew describes in *Wratsch* (Nos. 17 and 18), a method invented by him to assist in the diagnosis of vesical calculi, which is simple, absolutely harmless and effective, especially for children. The patient in the dorsal position, knees flexed, the physician on the right side introduces his right forefinger per rectum as far as the bladder, the volar side up and bends it rapidly several times as if beckoning with the two lower phalanges, hitting each time the floor of the bladder. If there is a non-encysted stone in the bladder it will be flung up by this motion and be felt when it falls down against the finger again. The bladder should not contain more than 150 c.c. of urine; the pelvis should be raised if more convenient; the investigation can not be continued long at a time as the sphincter ani constricts the finger and deadens the sensibility; the finger must work gently at first not to push the stone away from the median line. It should be tossed up as perpendicularly as possible to render its fall more distinct. The patient himself sometimes feels the rise and fall of the stone. There is no contra indication to the use of this test except tendency to hemorrhage.—*St. Petersb. med. Woch.*, July 17.

A Method of Indefinitely Keeping up the Circulation of Blood in the isolated heart of a frog has been devised by Prof. C. G. Santesson of Stockholm, with which he has succeeded in keeping the heart pulsating for eight hours with a 15 centimeter inflow and an 18 outflow, pumping at each pulsation 0.25 c.c. at first and 0.2 at the close of the experiment, which could have been continued longer if desired—a total of 4.7 liters. The apparatus is extremely simple, merely two large glass cylinders (Mariotte) suspended at a certain distance above the isolated heart, which is in an air tight box partly filled with salt solution, with which they connect by a single tube with faucets, etc. The aorta tube passes out of the heart to a receptacle suspended above just below the blood cylinders, one of which is filled with normal blood while the other serves for toxicologic experimentation. Both the aorta and the vena cava tubes are connected with registering drums, and the heart box by a tube with the Ellis piston recorder. An electric device records the seconds and the four pencils write simultaneously on a Ludwig Baltzar kymographion. The *Cbl. f. Phys.*, of July 10, Vol. 9, No. 8, contains the complete illustrated description.

Physiologic Connection Between the Nerves of the Heart and the Thyroid Gland.—Prof. E. v. Cyon has resumed his important studies of the depressor nerve (horses, dogs and rabbits) and now announces: 1. That stimulation of the third root, which anastomoses with the superior cervical ganglion, diminishes the blood pressure very much by reflex action, usually accompanied by an acceleration of the cardiac impulses. He has never observed the opposite effect with this isolated stimulation, even when both vagi were intact. The pupils are frequently noticeably contracted and continue thus for a while after the irritation. 2. The root of the depressor nerve arising in the superior laryngeal nerve, serves principally to connnect the heart with the thyroid and enables it to directly control the action of the gland. The nerve fibers passing from the inferior laryngeal to the heart probably answer the same physiologic purpose. 3. Baumann's thyroiodin introduced directly into the circulation affects the nerves of the heart and the vessels, especially the depressor nerve, to a marked extent. Stimulation of the depressor after the introduction of thyroiodin causes a violent diminution of the blood pressure in many cases from which the animal is unable to rally and dies from lack of blood in the heart. He concludes his communication to the *Cbl. f. Phys.* of July 10 by stating that the anatomic and physiologic relations between the nerves of the heart and the thyroid, through the mediation of the depressor nerve, clearly explains the etiology of Basedow's disease and also of the strumous affections originating in overexertion of the heart or violent emotions.

X-Ray Photography.—J. Tarchanow has found that the body is protected from the electric effect of the Crookes' tube by placing a thin sheet of aluminum over it. It allows the passage of the X-ray, but arrests the gentle electric discharges which emanate from the Crookes' tube to quite a distance, as he has proved with frogs intoxicated with strychnin, which pass into a tetanic condition when approached to 2 or 3 cm. of the tube, if held with the nerves parallel to it. The muscles are not affected, nor the nerves, if perpendicular (*St. P. Med. Woch.*, July 17, from *Gas. Botkina*, No. 13). Foveau de Courmelles states that the more serious accidents following the use of the Crookes' tubes are caused by radiography, which requires slow vibrations, while the slighter accidents are produced by radioscopy, with which the vibrations are rapid, although the seances may be much longer and more numerous. He also asserts that a small inert Crookes' tube is acted upon by a stronger one in action, even at quite a distance. It becomes luminous also with stratified light. There is a series of discharges in a vacuum tube similar to the rapid discharges of condensers, which is Professor d'Arsonval's "high frequency." With this, the limits of sensibility once passed, the organism ceases to feel them, while still undergoing their curative effects. The action of the X-ray is analogous to this, and depends upon the rapidity with which it is obtained. By controlling this, we will secure a special autoconduction whose physiologic and therapeutic action can be regulated as desired. —Soc. de Biol., July 17, *Presse Méd.*, July 21.

Microbes and Thromboses in the Placenta.—Delore of Lyons has found microbes of several varieties invariably present in the placenta, and also has established the fact that the fetal side is always more or less covered with thromboses, to which he ascribes the rôle of safety filter, preventing the passage of the microbes into the fetus. His communication to the Acad. de Méd. contains observations of various cases of apparently healthy mothers with healthy infants in which streptococci were found occasionally in the placentæ, and almost always micro-, diplo- and staphylo-cocci. The microbes were found clustered in the thromboses, which he confirmed with experiments on animals. He deduces the practical conclusions that the prolonged presence of these microbes in reserve is a perpetual menace to the health of the mother, as they may at any moment determine an auto-intoxication which would be erroneously attributed to contagion. Again, in delivering the placenta it is of the utmost importance not to lacerate it, and thus free the microbes held in the thromboses.—*Bulletin*, July 20.

Lord Kelvin on Contact Electricity.—At the Royal Institution Lord Kelvin recently gave a most important lecture. He began by showing an experiment which conclusively proved Volta's theory that, when a zinc plate and a copper plate were put in contact, one became charged with positive electricity and the other with negative. Although he had shown this experiment fifty years ago at Glasgow University, says the *Builder*, yet an immense amount of ingenuity had been wasted recently in trying to explain away this phenomenon. He considered that Volta was absolutely right and made an appeal to physicists to study Volta's work seriously. A very interesting and novel experiment was shown. A plate of uranium was connected to one terminal of an electrometer, and was then touched by a plate of aluminum. It was seen by the deflection of the spot of light that the uranium plate became at first positively electrified; it then gradually lost its charge and became negatively electrified. Lord Kelvin could suggest no explanation of this very mysterious experiment. Another interesting topic touched upon was Becquerel's discovery of the radiation given off by uranium. This radiation is very feeble, but photographs of coins, etc., taken by its means were thrown on a screen. He stated that it had been conclusively proved that this radiation was not due to phosphorescence, or the slow radiation of light previously absorbed, and he could give no explanation of it. Lord Kelvin was slightly discursive, but he was listened to most eagerly, and his points were rapidly taken up by an appreciative audience.—*Scientific American.*

Honors Awarded to the Profession in France.—The town of Bresches has erected a statue to Velpeau (born there in 1795, the son of a blacksmith), who "by his works and discoveries placed France in the front rank in the world of science." The building in Paris which Pasteur occupied as a laboratory for many years has been marked with a medallion and inscription, giving the dates of his various discoveries made there. A monument has also been started for Pelletier and Caventou, "to whom we owe the discovery of quinin." Dr. Reech and Dr. Cuneo have been made Commanders of the Legion of Honor, and several others, officers. A gold medal has been presented to Dr. Recamier of Paris for his services at the Charity Bazar horror, with honorable mention of others. We note the above in one single issue of the *Progrès Médical*, evidences of the French policy of rewards for skill and devotion, found in every trade and profession, and which has developed artists out of artisans and aided materially in the progress of science.

Gastrectomy for Neoplasm of the Stomach.—At a recent meeting of the Paris Academy of Medicine, Péan (*Gaz. hebd. de Méd. et de Chir.*, July 18, 1897, page 679) reported the case of a man 56 years old who came under observation on account of a tumor of the stomach, associated with hematemesis and pronounced cachexia. Celiotomy exposed a new growth occupying the pylorus and the right half of the stomach. The neoplasm was excised between forceps placed five centimeters beyond the limits of the growth, the lower five-sixths of the wound closed with silk sutures, a Murphy button introduced into the remainder and union established with the duodenum. The abdominal wound was closed with sutures in three stages, the last uniting the omentum with the parietal peritoneum. Then the cutaneous wound was closed. The further course of the case was uncomplicated. Appetite returned and the patient gained in strength and eleven pounds in weight.

The Calot Method of Reducing Curvature of the Spine by Forcible Pressure.—M. Brun reports the death of a child of four during this operation but states that the fatality was due to the chloroform narcosis, which is extremely difficult to carry out in this operation as the litttle patient lies on his face and respiration is more or less seriously affected. Prof. C. Willems of Ghent contributes an article to the *Semaine Méd.*, of July 28 on this subject, in which he states that the narcosis is unnecessary and dangerous, and that the operation is equally if not more effective without it, while the pain is not excessive. The operation itself has upset all our preconceived notions of handing Pott's disease, and the fact that the forcible reduction of the curvature is not particularly painful is only one more astonishing feature. The child seems to object more to the forcible traction of the assistants than to the pressure on his back, crying: "Don't pull so!" rather than the scream of pain that might be expected. Willems reports eighteen cases thus treated without an anesthetic; the results were more than satisfactory in each case (ages two to four; oldest curvature five years). He recommends the operation to all, and adds that relaxation of the muscles is secured much more effectively by the fatigue of the traction than with a narcotic, as the effects of the latter are just passing away when the plaster corset is being applied, when the relaxation is most important; while without a narcotic, the muscles are at that time in the most relaxed condition from fatigue. He has seen more than one child fall asleep from fatigue the moment the tractions ceased. He concludes by observing that more assistants are required (six to eight), but that this is all and any physician can now undertake this simple reduction of the *gibbosités pottiques* alone, without other assistance than he finds in the patient's family, or any special apparatus except the Calot plaster corset, to immobilize the straightened spine.

Notes of a Gynecologist's Tour of Europe.—Asepsis is driving out antisepsis, and with it drainage. Carbolic acid has nearly disappeared. Formalin is taking the place of sublimate, and ordinary dry sterile gauze of iodoform gauze. My general impression is that the French method of extirpating the uterus or adnexa or both, per vaginam, is winning its way more and more. In regard to disinfecting the hands, Kümmell of Hamburg and Sänger of Leipsic, first scrub the hands with green soap and sand for five minutes, then with alcohol, and finally dip them in a stong solution of sublimate. Separate rooms are provided for celiotomies in Hamburg and Dresden. Müller of Berne makes his incision for celiotomy not on the median line but a centimeter to the right or left. Martin lays a common sponge dipped in boiled oil in the abdominal cavity to prevent adhesions. Prochownick uses submucous injections of cocain and morphin instead of general narcosis, especially in sutures of the intestines, to prevent vomiting. Bumm of Basel does not drain in abdominal nor vaginal operations. Leopold uses dry gauze for draining; Aubeau a drain tube; Schauta of Vienna, iodoform gauze, and in London the old glass drainage tubes are still used. Sänger, Ohlhausen and Chrobak do not drain at all, and Pestalozzi and Jacobs only through the vagina, and not unless there is a large pus accumulation in the abdominal cavity. Catgut is used by Prochownick and the Berlin school exclusively, usually boiled in a 5 per cent. solution of carbolic acid in 80 per cent. alcohol. Silk is preferred by Kümmell; Sänger, except for buried sutures in vaginal wall; and by Freund, with silver wire for abdominal sutures. Zweifel and Leopold use dry gauze; Sänger moistens it with a sterile soda solution, Jacobs of Brussels disinfects the vagina with: 1, a saturated solution of green soap and alcohol; 2, a solution of sodium biborate and ammonium carbonate; 3, alcohol, and 4, formalin, 1 to 1500. A fatal case of iodoform intoxication in his practice has caused him to abandon iodoform gauze and use only the ordinary sterile article. Vaginofixation is very common in Berlin, even for prolapsus, and is also practiced by Rosthorn of Prague, and Schauta for retroversio. Sänger has observed seventeen normal pregnancies and deliveries in seventy cases of ventrofixation for retroversio. In Paris a modified ventrofixation is practiced; each side of the uterus is sutured with silk to the correspoding fascia and muscles. Jacobs rejects ventrofixation for retroversio. His method is to free the uterus from adhesions through the posterior vaginal wall, and Douglas's pouch, and then close the incision. The anterior wall is then incised from right to left and the peritoneum opened. The anterior wall of the uterus is then sutured with silk to the peritoneum covering the anterior vaginal wall. Normal child-bearing occurs with this operation, the uterus retaining its position. He recently found that only three out of seventy patients had survived four years after vaginal hysterectomy for carcinoma uteri. London is far behind the Continent in asepsis.—From J. Wiener's address on the "Present Status of Gynecology in Europe." *N. Y. med. Monatsschrift*, July 20.

Gleanings.—Obstinate ozena of long standing cured with antidiphtheria serum, three cases (Molinié).—Faradization effective in curing pruritus vulvæ. *Semaine Méd.*, July 14. . . Roentgen ray does not affect the Koch bacillus, but two cases of tuberculosis have been strikingly improved by treatment with it, evidently due to the direct effect of the ray on the lung tissue, similar to its known effect upon the skin. *Bul. de l'Acad. de Méd.*, July 13. . . Injections of purgative waters recommended for constipation in infants and children. One tablespoon to the year (up to 7) in a pint or half pint of tepid boiled water.—Spanish physician (Mascaro) has trained a blind man to use the bicycle, following a seeing leader, and proposes to train others to use tandems. *Gaz. Méd. de Liège*, July 15. . . Syphilis appearing in the third generation; two cases: choroiditis and keratitis. *Ann. de Derm.*, June. . . Needle broken off in wrist drawn into palm of hand and extracted by use of weak magnet alone; nine seances, twenty hours in all.—Burns promptly and radically cured with a concentrated solution of potassium permanganate applied immediately and kept on several minutes. *Progrès Méd.*, July 17. . . Serum in pneumococcus infections found to possess the agglutinative power. *Presse Méd.*, July 17. . . The University and municipality of Berlin have each erected a Roentgen laboratory. *Therap. Woch.*, July 18. . . Silk recommended for bandages for rheumatic joints.—Case of pulsating exophthalmus after fracture of basis cranii. *Deutsche med. Woch.*, July 8. . . Anteflexion of the epiglottis corroborative symptom of syphilis. *Ann. de Derm.*, June. . . Hypertrophied, painful breasts relieved and restored to normal shape by cutting out a rectangular piece of top (not wedge-shaped) and suturing to the aponeurosis of the pectoralis major. *Presse Méd.*, July 10. . . Fatal case of fluid from intra-uterine injections passing into the abdomen. Six experimental injections of colored fluids just before hysterectomy showed the fluid in the abdominal cavity in each case where the tube ends were open, and collected at the end where they were closed. *German Gyn. Congress.* . . Heidenhain begs internal therapeutists to keep track of the patients cured of intestinal occlusion by medication alone, to note relapses. *Therap. Woch.*, July 11.

Hospitals.

The National Sanitarium for Consumptives, the first of its kind in Canada, was opened at Gravenhurst, Ontario, August 21. There is accommodation for 100 patients, the buildings standing 500 feet above Lake Ontario, on a plot of fifty acres, sheltered by low rocky ranges on each side, and so constructed that every room will have sunlight when the sun shines.—— A new wing has been added to Hamot Hospital, Erie, Pa., through a donation from the late George Selden——The Presbyterian Hospital, Milwaukee, is to be consolidated with St. Joseph's Hospital, and a new building erected for the Wisconsin College of Physicians and Surgeons on a site opposite St. Joseph's.

THE PUBLIC SERVICE.

Navy Changes. Changes in the Medical Corps of the U. S. Navy for the week ending August 28, 1897.

Asst. Surgeon W. M. Wheeler, detached from the "*Marietta*" and ordered to the "Wheeling" September 2.

P. A. Surgeon G. Rothganger, detached from the "Wheeling" and ordered to the "Marietta" September 2.

CHANGE OF ADDRESS.

Cutter, E. and J. A., from Mott Av. and 165th St. to 1054 Boston Road, New York, N. Y.

Dandridge, N. P., from 53 E. 4th St. to 422 Broadway, Cincinnati, Ohio. Davidson, T. W., from Oneida to Galesburg, Ill.; Demaree, T. E., from Rossville to Claytonville, Ill.

Foreman, J. M., from Jonesburgh to 4128 Easton Av., St. Louis, Mo.; Foskett, W. A., from 391 N. Ashland Av. to 1556 Milwaukee Av., Chicago, Ill.; Frederick, R. C., from 1900 Dearborn Av. to 506 State St., Chicago, Ill. Fuhrman, E. H., from New London to Grafton, Wis.

Gihon, A. L., from Sykesville, Md. to "Reform Club" 233 Fifth Av., New York, N. Y.; Gilbert, M. J., Willard, N. Y.

Haldenstein, J., from 32 Beaver St. to 19 Seymour Bldg., cor. 42d St. and Fifth Av., New York, N. Y.

Keir, W. F., from 309 S. [illegible] t. Louis, Mo.

Lockwood, W. D., from [illegible] Mo.

Mennett, O. H., from U[illegible] l.; *McBride, R. E.*, from Gibson City to Houma, La.; McKinnon, J. R., from 275 Ontario St. to 313 Chicago Av., Chicago, Ill.

Ross, Thos. D., from Ferndale to Mayfield, Ill.

Seeman, F. A., from Chicago, Ill., to Dubuque, Ia.

Washington, S. S. H., from Tuskeegee to Birmingham, Ala.

LETTERS RECEIVED.

ADDRESS.

ADDRESS IN MEDICINE.

At the Sixty-fifth Annual Meeting of the British Medical Association, Montreal, Aug. 31 to Sept. 4, 1897.

BY WILLIAM OSLER, M.D., F.R.C.P.

PROFESSOR OF MEDICINE, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

[From advance sheets of the *British Medical Journal.*]

BRITISH MEDICINE IN GREATER BRITAIN.—THE MAKING OF GREATER BRITAIN.

To trace successfully the evolution of any one of the learned professions would require the hand of a master, of one who, like Darwin, could combine the capacity for patient observation with philosophic vision. In the case of medicine the difficulties are enormously increased by the extraordinary development which belongs to the history of the present century. The rate of progress has been too rapid for us to appreciate, and we stand bewildered, and, as it were, in a state of intellectual giddiness, when we attempt to obtain a broad comprehensive view of the subject. In a safer "middle flight" it is my purpose to dwell on certain of the factors which have molded the profession in English-speaking lands beyond the narrow seas—of British Medicine in Greater Britain. Even for this lesser task (though my affiliations are wide and my sympathies deep) I recognize the limitations of my fitness, and am not unaware that in my ignorance I shall overlook much which might have rendered less sketchy a sketch necessarily imperfect.

Evolution advances by such slow and imperceptible degrees that to those who are part of it the finger of time scarcely seems to move. Even the great epochs are seldom apparent to the participators. During the last century neither the colonists nor the mother country appreciated the thrilling interest of the long-fought duel for the possession of this continent. The acts and scenes of the drama, to them detached, isolated and independent, now glide like dissolving views into each other, and in the vitascope of history we can see the true sequence of events. That we can meet here today, Britons on British soil in a French province, is one of the far off results of that struggle. This was but a prelude to the other great event of the eighteenth century, the revolt of the colonies and the founding of a second great English speaking nation—in the words of Bishop Berkeley's prophecy, "Time's noblest offspring."

Surely a unique spectacle that a century later descendants of the actors of these two great dramas should meet in an English city in New France. Here the American may forget Yorktown in Louisburg, the Englishman Bunker Hill in Quebec, and the Frenchman both Louisburg and Quebec in Chateauguay; while we Canadians, English and French, in a forgiving spirit, overlooking your unseemly quarrels, are only too happy to welcome you to our country, this land on which, and for which, you have so often fought. Once, and only once, before in the history of the world could such a gathering as this have taken place. Divided though the Greeks were, a Hellenic sentiment of extraordinary strength united them in certain assemblies and festivals. No great flight of imagination is required to picture a notable representation of our profession in the fifth century B. C. meeting in such a colonial town as Agrigentum under the presidency of Empedocles. Delegates from the mother cities, brilliant predecessors of Hippocrates of the stamp of Damocedes and Herodicus, delegates from the sister colonies of Syracuse and other Sicilian towns, from neighboring Italy, from far distant Massilia, and from still more distant Panticapæum and Istra. And in such an assemblage there would have been men capable of discussing problems of life and mind more brilliantly than in many subsequent periods, in proportion as the pre Hippocratic philosophers in things medical had thought more deeply than many of those who came after them.

We English are the modern Greeks, and we alone have colonized as they did, as free people. There have been other great colonial empires, Phœnician, Roman, Spanish, Dutch and French, but in civil liberty and in intellectual freedom Magna Græcia and Greater Britain stand alone. The parallel so often drawn between them is of particular interest with reference to the similarity between the Greek settlements in Sicily and the English plantations on the Atlantic coast. Indeed, Freeman says, "I can never think of America without something suggesting Sicily, or of Sicily without something suggesting America." I wish to use the parallel only to emphasize two points, one of difference and one of resemblance. The Greek colonist took Greece with him. Hellas had no geographical bounds. "Massilia and Olbia were cities of Hellas in as full a sense as Athens or Sparta." While the emigrant Britons changed their sky, not their character, in crossing the great sea, yet the home stayers had never the same feelings toward the plantations as the Greeks had toward the colonial cities of Magna Græcia. If, as has been shrewdly surmised, Professor Seely was Herodotus reincarnate, how grieved the spirit of the "Father of History" must have been to say of Englishmen, "Nor have we even now ceased to think of ourselves as simply a race inhabiting an island off the northern coast of the continent of Europe." The assumption of gracious superiority which, unless carefully cloaked, smacks just a little of our national arrogance, is apt to jar on sensitive colonial nerves. With the expansion of the empire, and the supplanting of a national by an imperial spirit, this will become impossible. That this sentiment never prevailed in Hellas, as it did later in the Roman empire, was due largely to the fact that in literature, in science, and in art the colonial cities of Greece early overshadowed the mother cities. It may be because the settlements of Greater Britian were things of slower growth, that it took several generations and several bitter trials to teach a lesson the Greeks never had to learn.

The Greek spirit was the leaven of the old world, the working of which no nationality could resist. Thrice it saved Western civilization, for it had the magic power of leading captivity captive, and making even captive conquerors the missionaries of culture. What modern medicine owes to it will appear later. "The love of science, the love of art, the love of freedom, vitally correlated to each other and brought into organic union" were the essential attributes of the Greek genius (Butcher). While we can not claim for the Anglo Saxon race all of these distinctions, it has in a high degree that one which in practical life is the most valuable, and which has been the most precious gift of the race to the world—the love of freedom.

> Of freedom in her regal seat
> Of England.

It would carry one too far afield to discuss the difference between the native Briton and his children scattered so widely up and down the earth. In Canada, South Africa, Australia and New Zealand, types of the Anglo Saxon race are developing which will differ as much from each other and from the English as the American does today from the original stock; but amid these differences can everywhere be seen those race qualities which have made us what we are—"courage, national integrity, steady good sense, and energy in work." At a future meeting of the Association, perhaps in Australia, a professional Sir Charles Dilke, with a firm grasp on the subject, may deal with the medical problems of Greater Britain in a manner worthy of the address in medicine. My task, as I mentioned at the outset, is much less ambitious.

THE INFLUENCE OF GREECE ON BRITAIN.

Could some one with full knowledge patiently analyse the characteristics of British medicine he would find certain national traits, sufficiently distinct for [illegible] itior [illegible] ree centuries can not do very much—and [illegible] just passed since the revival of medici [illegible] ocal conditions of isolation, which have been singularly favorable to the development of special peculiarities in the national character, have not been without effect on the medical profession. I can not do more than touch upon a few features, not distinctive but illustrative—features which will be useful as indicating the sources of influence upon Greater Britain in the past, and which may, perhaps, be suggestive as to lines of progress in the future.

Above the fireplace in Sir Henry Acland's study are three paneled portraits of Linacre, Sydenham and Harvey; the scroll upon them reads *Literæ*, *Praxis*, *Scientia*. To this great triumvirate, as to the fountain heads, we may trace the streams of inspiration which have made British medicine what it is today.

Linacre, the type of the litery physician, must ever hold a unique place in the annals of our profession. To him was due in great measure the revival of Greek thought in the sixteenth century in England, and in the last Harveian Oration Dr. Payne has pointed out his importance as a forerunner of Harvey. He made Greek methods available; through him the art of Hippocrates and the science of Galen became once more the subject of careful, first-hand study. Linacre, as Dr. Payne remarks, "was possessed from his youth till his death by the enthusiasm of learning. He was an idealist, devoted to objects which the world thought of little use." Painstaking, accurate, critical, hypocritical, perhaps, he remains today the chief literary representative of British medicine. Neither in Britain nor in Greater Britain have we maintained the place in the world of letters created for us by Linacre's noble start. It is true that in no generation since has the profession lacked a man who might stand unabashed in the temple at Delos; but, judged by the fruits of learning, scholars of his type have been more common in France and Germany. Nor is it to our credit that so little provision is made for the encouragement of these studies. For years the reputation of Great Britain in this matter was sustained almost alone by the great Deeside scholar, the surgeon of Banchory, Francis Adams, the interpreter of Hippocrates to English students. In this century he and Greenhill have well maintained the traditions of Linacre. Their work, and that of a few of our contemporaries, among whom Ogle must be specially mentioned, has kept us in touch with the ancients. But by the neglect of the study of the humanities, which has been far too general, the profession loses a very precious quality.

While in critical scholarship and in accurate historical studies British medicine must take a second place, the influence of Linacre, exerted through the Royal College of Physicians and the old Universities, has given to the humanities an important part in education, so that they have molded a larger section of the profession than in any other country. A physician may possess the science of Harvey and the art of Sydenham, and yet there may be lacking in him those finer qualities of heart and head which count for so much in life. Pasture is not everything, and that indefinable, though well understood, something which we know as breeding is not always an accompaniment of great professional skill. Medicine is seen at its best in men whose faculties have had the highest and most harmonious culture. The Lathams, the Watsons, the Pagets, the Jenners and the Gairdners have influenced the profession less by their special work than by exemplifying those graces of life and refinements of heart which make up character. And the men of this stamp in Greater Britain have left the most enduring mark: Beaumont, Bovell, and Hodder in Toronto; Holmes, Campbell and Howard in this city; the Warrens, the Jacksons, the Bigelows, the Bowditches and the Shattucks in Boston; Bard, Hossack, Francis, Clark and Flint in New York; Morgan, Shippen, Redman, Rush, Coxe, the elder Wood, the elder Pepper, and the elder Mitchell in Philadelphia—Brahmins all, in the language of the greatest Brahmin among them, *Oliver Wendell Holmes*—these, and men like unto them, have been the leaven which has raised our profession above the dead level of a business.

The *literæ humaniores* represented by Linacre, revived Greek methods, but the faculty at the end of the sixteenth and the beginning of the seventeenth centuries was in a slough of ignorance and self-conceit, and not to be aroused even by Moses and the prophets in the form of Hippocrates and the fathers of medicine.

In the pictures referred to Sydenham is placed between Linacre and Harvey, but science preceded practice, and Harvey's great Lumleian Lectures were delivered before Sydenham was born. Linacre has been well called by Payne Harvey's intellectual grandfather. "The discovery of the circulation of the blood was the climax of that movement which began a century and a half before with the revival of Greek medical classics and especially of Galen" (Payne). Harvey returned to Greek methods and became the founder of modern experimental physiology and the great glory of British scientific medicine. The demonstration of the circulation of the blood remains in every detail a model research. I shall not repeat the oft-told tale of Harvey's great and enduring influence, but I must refer to one feature which, until lately, has been also a special characteristic of his direct successors in Great Britain. Harvey was a practitioner and hospital physician. There are gossiping statements by Aubrey to the effect that "he fell mightily in his practice" after the publication of the "De Motu Cordis," and that his "therapeutic way" was not admired; but to these his practical success is the best answer. It is remarkable that a large proportion of all the physiologic work of Great Britain has been done by men who have become successful hospital physicians and surgeons. I was much impressed by a conversation with Professor Ludwig in 1884. Speaking of the state of English physiology, he lamented the lapse of a favorite English pupil from science to practice; but he added, "while sorry for him, I am glad for the profession in England." He held that the clinical physicians of that country had received a very positive impress from the work of their early years in physiology and the natural sciences. I was surprised at the list of names which he cited—among them I remember Bowman, Paget, Savory and Lister. Ludwig attributed this feature in part to the independent character of the schools in England, to the absence of the university element, so important in medical life in Germany, but, above all, to the practical character of the English mind, the better men preferring an active life in practice to a secluded laboratory career.

Thucydides it was who said of the Greeks that they possessed "the power of thinking before they acted, and of acting too." The same is true in a high degree of the English race. To know first what has to be done, then to do it, comprises the whole philosophy of practical life. Sydenham (*Angliæ lumen*, as he has been well called) is the model practical physician of modern times. Linacre led Harvey back to Galen, Sydenham to Hippocrates. The one took Greek science, the other not so much Greek medicine as Greek methods, particularly intellectual fearlessness, and a certain knack of looking at things. Sydenham broke with authority and went to Nature. It is an extraordinary fact that he could have been so emancipated from dogmas and theories of all sorts. He laid down the fundamental proposition, and acted upon it, that "all diseases should be described as objects of natural history." To do him justice we must remember, as Dr. John Brown says, "in the midst of what a mass of errors and prejudices, of theories actively mischievous, he was placed, at a time when the mania of hypothesis was at its height, and when the practical part of his art was overrun and stultified by vile and silly nostrums."

Sydenham led us back to Hippocrates; I would that we could be led oftener to Sydenham. How necessary to bear in mind what he says about the method of the study of medicine. "In writing, therefore, such a natural history of diseases, every merely philosophical hypothesis should be set aside, and the manifest and natural phenomena, however minute, should be noted with the utmost exactness. The usefulness of this procedure can not be easily over-rated as compared with the subtle inquiries and trifling notions of modern writers, nor can there be a shorter, or indeed any other way of coming at the morbific causes, or of discovering the curative indications, than by a certain perception of the peculiar symptoms? By these steps and helps it was that the father of physic, the great Hippocrates, came to excel, his theory being no more than an exact description or view of Nature. He found that Nature alone terminates diseases, and works a cure with a few simple medicines, and often enough with no medicines at all." Well, indeed, has a recent writer remarked, "Sydenham is unlike every previous teacher of the principles and practice of medicine in the modern world."

Sydenham—not Linacre or Harvey—is the model British physician, in whom were concentrated all these practical instincts upon which we lay such stress in the Anglo-Saxon character. The Greek faculty which we possess of thinking and acting has enabled us, in spite of many disadvantages, to take the lion's share in the great practical advances in medicine. The three greatest scientific movements of the century have come from Germany and France. Bichat, Laennec and Louis laid the foundation of modern clinical medicine; Virchow and his pupils of scientific pathology; while Pasteur and Koch have revolutionized the study of the causes of disease; and yet the modern history of the art of medicine could almost be written in its fulness from the records of the Anglo-Saxon race. We can claim almost every practical advance of the very first rank—vaccination, anesthesia, preventive medicine and antiseptic surgery—the "captain jewels in the carcanet" of the profession, beside which can be placed no others of equal luster.

THE INFLUENCE OF AUTHORITY IN MEDICINE.

One other lesson of Sydenham's life needs careful conning. The English Hippocrates, as I said, broke with authority. His motto was:

> Thou, nature, art my goddess; to thy law
> My services are bound.

Undue reverence for authority as such, a serene satisfaction with the *status quo* and a fatuous objection to change, have often retarded the progress of medicine. In every generation, in every country there had been, and ever will be, *laudatores temporis acti*, in the bad sense of that phrase, not a few of them men in high places, who have lent the weight of a complacent conservatism to bolster up an ineffectual attempt to stay the progress of new ideas. Every innovator from Harvey to Lister has been made to feel its force. The recently issued life of Thomas Wakley is a running commentary on this spirit, against the pricks of which he kicked so hard and so effectually. But there are signs of a great change. The old universities and the colleges, once the chief offenders, have been emancipated, and remain no longer, as Gibbon found them, steeped in port and prejudice. The value of authority *per se* has lessened enormously, and we of Greater Britain have perhaps suffered as the pendulum has swung to the other extreme. Practice loves authority, as announced in "the general and perpetual voice of men" (Hooker). Science must ever hold with Epicharmus that a judicious distrust and a wise skepticism are the sinews of the understanding. And yet the very foundations of belief in almost everything relating to our art rest upon authority. The practitioner can not always be the judge, the responsibility must often rest with the teachers and investigators, who can only learn in the lessons of history the terrible significance of the word.

In the treatment of fever the fetters of a thousand years were shattered by Sydenham—shattered only to be riveted anew. How hard was the battle in this century against the intrenched and stubborn foe. Listen to the eloquent pleadings of Stokes, pleading, as did Sydenham, against authority, and against the bleedings, the purgings and sweatings of fifty years ago. "Though his hair be gray, and his authority high, he is but a child in knowledge and his reputation an error. On a level with the child, so far as correct appreciation of the great truths of medicine is concerned, he is very different in other respects; his powers of doing mischief are greater; he is far more dangerous. Oh! that men would stoop to learn, or at least cease to destroy." The potency of human authority among the "powers that be" was never better drawn than by the judicious Hooker in his section on this subject: "And this not only with the 'simpler sort,' but the learneder and wiser we are, the more such arguments in some cases prevail with us. The reason why the simpler sort are moved with authority is the conscience of their own ignorance; whereby it cometh to pass that having learned men in admiration, they rather fear to dislike them than know wherefore they should allow and follow their judgments. Contrariwise with them that are skilful, authority is much more strong and forcible; because they only are able to discern how just cause there is why to some men's authority so much should be attributed. For which cause the name of Hippocrates (no doubt) were more effectual to persuade such men as Galen himself than to move a silly empiric."[1]

Sydenham was called "a man of many doubts," and therein lay the secret of his great strength.

MEDICINE IN AMERICA: TO 1820.

Turning now to the main question of the development of this British medicine in Greater Britain, I must at once acknowledge the impossibility of doing justice to it. I can only indicate a few points of importance, and I must confine my remarks chiefly to the American part of Greater Britain.

We may recognize three periods, corresponding to three distinct waves of influence: the first from the early migrations to about 1820; the second from about 1820 to 1860; and the third from about 1860 to the present time.

The Colonial settlements were contemporaneous with the revival of medicine in England. Fellow-students of Harvey at Cambridge might have sailed in the *Mayflower* and the *Arbella*. The more carefully planned expeditions usually enlisted the services of a well trained physician, and the early records, particularly of the New England colonies, contain many interesting references to these college-bred men. Giles Firman, who settled in Boston in 1632, a Cambridge man, seems to have been the first to give instruction in medicine in the new world. The parsons of that day had often a smattering of physic, and illustrated what Cotton Mather called an "angelical conjunction." He says: "Ever since the days of Luke, the Evangelist, skill in physick has been frequently professed and practiced by persons whose more declared business was the study of divinity." Firman himself finding physic "but a meane helpe," took orders. These English physicians in the New England colonies were scholarly, able men. Roger Chillingworth, in Hawthorne's "Scarlet Letter," has depicted them in a sketch of his own life: "Made up of earnest, studious, thoughtful, quiet years, bestowed faithfully for the increase of knowledge; faithfully, too, for the advancement of human welfare; men thoughtful for others, caring little for themselves, kind, just, true, and of constant if not warm affections"—a singularly truthful picture of the old colonial physician.

Until the establishment of medical schools—University of Pennsylvania, 1763; King's College (afterward Columbia) 1767; and Harvard, 1782—the supply of physicians for the colonies came from Great Britain, supplemented by men trained under the old apprentice system, and of colonists who went to Edinburgh, Leyden and London for their medical education. This latter group had a most powerful effect in molding professional life in the pre-revolutionary period. They were men who had enjoyed not alone the instruction, but often the intimate friendship of the great English and European physicians. Morgan, Rush, Shippen, Bard, Wistar, Hossack and others had received an education comprising all that was best in the period, and had acquired the added culture which can only come from travel and wide acquaintance with the world. Morgan, the founder of the medical school of the University of Pennsylvania, was away seven years, and before returning had taken his seat as a corresponding member of the French Academy of Surgery, besides having been elected a Fellow of the Royal Society. The war of Independence interrupted temporarily the stream of students, but not the friendship which existed between Cullen and Fothergill and their old pupils in America. The correspondence of these two warm friends of the colonies testifies to the strong professional intimacy which existed at the time between the leaders of the profession in the old and new worlds. But neither Boerhaave, Cullen, nor Fothergill stamped colonial medicine as did the great Scotchman, John Hunter. Long weary centuries separated Harvey from Galen; not a century elapsed from the death of the great physiologist to the advent of the man in whose phenomenal personality may be seen all the distinctive traits of modern medicine, and the range of whose mighty intellect has had few, if any, equals since Aristotle. Hunter's influence on the profession of this continent, so deep and enduring, was exerted in three ways. In the first place, his career as an army surgeon, and his writings on subjects of special interest to military men, carried his work and ways into innumerable campaigns in the long French wars, and the war of Independence. Hunter's works were reprinted in America as early as 1791 and 1793. In the second place, Hunter had a number of most distinguished students from the colonies, among whom were two who became teachers of wide reputation. William Shippen, the first Professor of Anatomy in the University of Pennsylvania, lived with Hunter on terms of the greatest intimacy. He brought back his methods of teaching, and some measure of his spirit. With the exception of Hewson and Home, Hunter had no more distinguished pupil than Philip Syng Physick, who was his House Surgeon at St. George's Hospital, and his devoted friend. For more than a generation Physick had no surgical compeer in America, and enjoyed a reputation equaled by no one save Rush. He taught Hunterian methods in the largest medical school in the country, and the work of his nephew (Dorsey) on surgery is very largely Hunter modified by Physick. But in a third and much more potent way the great master influenced the profession of this continent. Hunter was a naturalist to whom pathologic processes were only a small part of a stupendous whole, governed by law, but which could never be understood until the facts had been accumulated, tabulated, and systematized. By his example, by his prodigious industry, and by his suggestive experiments he led men again into the old paths of Aristotle, Galen and Harvey. He made all thinking physicians naturalists; he lent a dignity to the study of organic life and re established a close union between medicine and the natural sciences. Both in Britain and Greater Britain he laid the foundation of the great collections and museums, particularly those connected with the medical schools. The Wistar-Horner and the Warren Museums originated with men who had been greatly influenced by Hunter. He was, moreover, the intellectual father of that *interesting group of men on this side of the Atlantic, who,* while practicing as physicians, de[illegible] [illegible] labor to the study of natural history. [illegible] last century and during the first thirt[illegible] [illegible]ful practitioner was very often a [illegible]

I wish that time permitted me to do justice to the long list of men who have been devoted naturalists, and who have made contributions of great value. Benjamin Smith Barton, David Hossack, Jacob Bigelow, Richard Harland, John D. Godman, Samuel George Morton, John Collins Warren, Samuel L. Mitchell, J. Aiken Meigs and many others have left the records of their industry in their valuable works, and in the Transactions of the various societies and academies. In Canada many of our best naturalists have been physicians, and collections in this city testify to the industry of Holmes and McCullough. I was regretting the humanities a few minutes ago, and now I have to mourn the almost complete severance of medicine from the old natural history. To a man the most delightful recollections of whose studentship are the Saturdays spent with a preceptor who had a Hunterian appetite for specimens—anything from a trilobite to an acarus—to such a one across the present brilliant outlook comes the shadow of the thought that the conditions of progress will make impossible again such careers as those of William Kitchen Parker and William Carmichael McIntosh.

Until about 1820 the English profession of this continent knew little else than British medicine. After this date in the United States the ties of professional union with the old country became relaxed, owing in great part to the increase in the number of home schools, and in part to the development of an American literature. To 1820, 114 native medical books of all kinds had been issued from the press, and 131 reprints and translations, the former English, the latter almost exclusively French (Billings). Turning for a few minutes to the conditions of the profession in Canada during this period, I regret that I can not speak of the many interesting questions relating to the French colonies. I may mention, however, that with the earliest settlers physicians had come, and among the Jesuits, in their devoted missions, there are records of *donnés* (laymen attached to the service) who were members of the profession. One of these, René Goupil, suffered martyrdom at the hands of the Iroquois.[2]

Between the fall of Quebec in 1759 and 1820 the English population had been increased by the settlement of Upper Canada, chiefly by United Empire Loyalists from the United States, and after the war of 1812 by settlers from the old country. The physicians in the sparsely settled districts were either young men who sought their fortunes in the new colony or were army surgeons who had remained after the Revolutionary war or the war of 1812. The military element gave for some years a very distinctive stamp to the profession. These surgeons were men of energy and ability, who had seen much service and were accustomed to order, discipline and regulations. Sabine, in his "History of the Loyalists," refers to the Tory proclivities of the doctors, and says that they were not so much disturbed as the lawyers and clergymen. Still a good many of them left their homes "for conscience sake"; and Canniff, in his "History of the Profession in Upper Canada," gives a list of those known to have been among the United Empire Loyalists. The character of the men who controlled the profession of the new colony is well shown by the proceedings of the Medical Board, which was organized in 1819. Drs. Macaulay and Widmer, both army surgeons, were the chief members. The latter, who has well been termed the father of the profession in Upper Canada, a man of the very highest character did more than any one else to promote the progress of the profession, and throughout his long career his efforts were always directed to the proper channels. In looking through Canniff's most valuable work one is much impressed by the sterling worth and mettle of the old army surgeons, who in these early days formed the larger part of the profession. The minutes of the Medical Board indicate with what military discipline the candidates were examined. and the percentage of rejections has probably never been higher in the history of the province than it was in the first twenty years of the existence of the Board.

One picture on the canvas of those early days lingers in the memory, illustrating many of the most attractive features of a race which has done much to make this country what it is today. Widmer was the type of the dignified old army surgeon, scrupulously punctilious, and in every detail regardful of the proprieties of life. "Tiger" Dunlop may be taken as the very incarnation of that restless, roving spirit which has driven the Scotch broadcast upon the world. After fighting with the Connaught Rangers in the war of 1812, campaigning in India, clearing the Sangur of tigers—hence his sobriquet "Tiger"—lecturing on medical jurisprudence in Edinburgh, writing for *Blackwood*, editing the *British Press* and the *Telescope*, introducing *Beck's Medical Jurisprudence* to English readers, and figuring as director and promoter of various companies, this extraordinary character appears in the young colony as "Warden of the Black Forest" in the employ of the Canada Company. His life in the backwoods at Gairbraid, his "Noctes Ambrosianæ Canadenses," his famous "Twelve Apostles," as he called his mahogany liquor stand (each bottle a full quart), his active political life, his remarkable household, his many eccentricities—are they not all portrayed to the life in the recently issued "In the Days of the Canada Company"?

AMERICA: 1820–1860.

Turning now to the second period, we may remark in passing that the nineteenth century did not open very auspiciously for British medicine. Hunter had left no successor, and, powerful as had been his influence, it was too weak to stem the tide of abstract speculation with which Cullen, Brown and others flooded the profession. No more sterile period exists than the early decades of this century. Willan, a great naturalist in skin diseases, with a few others, save it from utter oblivion. The methods of Hippocrates, of Sydenham and of Hunter had not yet been made available in every day work. The awakening came in France, and such an awakening! It can be compared with nothing but the renaissance in the sixteenth and seventeenth centuries, which gave us Vesalius and Harvey. "Citizen" Bichât and Broussais led the way, but Laennec really created clinical medicine as we know it today. The discovery of auscultation was only an accident—of vast moment it is true—in a systematic study of the correlation of symptoms with anatomic changes. Louis, Andral and Chomel extended the reputation of the French school, which was maintained to the full until the sixth decade, when the brilliant Trousseau ended a long line of Paris teachers, whose audience had been world wide.

The revival of medicine in Great Britain was directly due to the French. Bright and Addison, Graves and Stokes, Forbes and Marshall Hall, Latham and Bennett were profoundly affected by the new movement. In the United States, Anglican influence did not wane until after 1820. Translations of the works of Bichât appeared as early as 1802, and there were reprints in subsequent years, but it was not until 1823 that the first translation of Laennec—a reprint of Forbes's edition—was issued. Broussais's works became very popular in translations after 1830, and in the journals from this time on the change of allegiance became very evident. But men rather than books diverted the trend of professional thought.

After 1825 American students no longer went to Edinburgh and London, but to Paris, and one can say that between 1830 and 1860 every teacher and writer of note passed under the Gallic yoke. The translations of Louis's works, and the extraordinary success of his American pupils—a band of the ablest young men the country has ever seen—added force to the movement. And yet this was a period in which American medical literature was made up largely of pirated English books, and the Systems, Encyclopedias, and Libraries, chiefly reprints, testify to the zeal of the publishers. Stokes, Graves, Watson, Todd, Bennett and Williams furnished Anglican pap to the sucklings, as well as strong meat to the full grown. In spite of the powerful French influence the textbooks of the schools were almost exclusively English.

In Canada the period from 1820 to 1860 saw the establishment of the English universities and medical schools. In Montreal the agencies at work were wholly Scotch. The McGill Medical School was organized by Scotchmen, and from its inception has followed closely Edinburgh methods. The Paris influence, less personal, was exerted chiefly through English and Scotch channels. The Upper Canada schools were organized by men with English affiliations and the traditions of Guy's, St. Bartholomew's, St. Thomas's, St. George's, and of the London Hospital rather than those of Edinburgh, have prevailed in Toronto and Kingston.

The local French influence in British medicine in Canada has been very slight. In the early decades of the century, when the cities were smaller and the intercourse between the French and English somewhat closer, the reciprocal action was more marked. At that period English methods became somewhat the vogue among the French; several very prominent French Canadians were Edinburgh graduates. Attempts were made in the medical journals to have communications in both languages, but the fusion of the two sections of the profession was no more feasible than the fusion of the two nationalities, and the development has progressed along separate lines.

AMERICA: 1860–1897.

The third period dates from about 1860, when the influence of German medicine began to be felt. The rise of the Vienna school was for a long time the only visible result in Germany of the French renaissance. Skoda, the German Laennec, and Rokitansky, the German Morgagni, influenced English and

American thought between 1840 and 1860, but it was not until after the last date that Teutonic medicine began to be felt as a vitalizing power, chiefly through the energy of Virchow. After the translation of the "Cellular Pathology" by Chance (1860) the way lay clear and open to every young student who desired inspiration. There had been great men in Berlin before Virchow, but he made the town on the Spree a Mecca for the faithful of all lands. From this period we can date the rise of German influence in the profession of this continent. It came partly through the study of pathologic histology under the stimulus given by Virchow, and partly through the development of the specialties, particularly diseases of the eye, of the skin, and of the larynx. The singularly attractive courses of Hebra, the organization on a large scale in Vienna of a system of graduate teaching, designed specially for foreigners, the remarkable expansion of the German laboratories, combined to divert the stream of students from France. The change of allegiance was a deserved tribute to the splendid organization of the German Universities, to the untiring zeal and energy of their professors, and to their single-minded devotion to science for its own sake.

MEDICINE IN AUSTRALASIA.

In certain aspects the Australasian settlements present the most interesting problems of Greater Britain. More homogeneous, thoroughly British, isolated, distant, they must work out their destiny with a less stringent environment than, for example, surrounds the English in Canada. The traditions are more uniform, and, of whatever character, have filtered through British channels. The professional population of native trained men is as yet small, and the proportion of graduates and licentiates from the English, Scotch and Irish Colleges and Boards guarantees the dominance of old country ideas. What the maturity will show can not be predicted, but the vigorous infancy is full of "crescent promise." On looking over the files of Australian and New Zealand journals one is impressed with the monotonous similarity of the diseases in the Antipodes to those of Great Britain and of this continent. Except in the matter of parasitic affections and snake bites, the nosology presents few distinctive qualities. The proceedings of the four Intercolonial Congresses indicate a high level of professional thought. In two points Australia has not progressed as other parts of Greater Britain. The satisfactory regulation of practice, so early settled in Canada, has been beset with many difficulties. Both in the United States and in Australia the absence of the military element, which was so strong in Canada, may, in part at least, account for the great difference which has prevailed in this matter of the State license. The other relates to the question of ethics, to which one really does not care to refer, were it not absolutely forced upon the attention in reading the journals. Elsewhere professional squabbles, always so unseemly and distressing, are happily becoming very rare, and in Great Britain and on this side of the water we try at any rate to wash our dirty linen at home. In the large Australian cities differences and dissensions seem lamentably common. Surely they must be fermented by the atrocious system of election to the hospitals, which plunges the entire profession every third or fourth year into the throes of a contest in which the candidates have to solicit the suffrages of from 2,000 to 4,000 voters. Well indeed might Dr. Batchelor, in his address to the Fourth Intercolonial Congress, say: "It is a scandal that in any British community, much less in a community which takes pride in a progressive spirit, such a pernicious system should survive for an hour."

MEDICINE IN HINDUSTAN.

Of India, of "Vishnu-land," what can one say in a few minutes? Three thoughts at once claim recognition. Here, in the dim dawn of history, with the great Aryan people, was the intellectual cradle of the world. To the Hindus we owe a debt which we can at any rate acknowledge, and even in medicine many of our traditions and practices may be traced to them, as as may be gathered from that most interesting "History of Aryan Medical Science," by the Thakore Sahib of Gondal.

Then there arises the memory of the men who have done so much for British medicine in this great empire. Far from their homes, far from congenial surroundings, and far from the stimulus of scientific influences, Annesley and Ballingall, Twining, Morehead, Waring, Parkes, Cunningham, Lewis, Vandyke Carter and many others have nobly upheld the traditions of Harvey and of Sydenham. On the great epidemic diseases how impoverished would our literature be in the absence of their contributions! But then there comes the thought of "the little done, the undone vast," when one considers the remarkable opportunities for study which India has presented. Where else in the world is there such a field for observation in cholera, leprosy, dysentery, the plague, typhoid fever, malaria, and in a host of other less important maladies? And what has the British Goverment done toward the scientific investigation of the diseases of India? Until recently little or nothing, and the proposal to found an institute for the scientific study of disease has actually come from the native chiefs. The work of Dr. Hankin and of Professor Haffkine, and the not unmixed evil of the brisk epidemic of plague in Bombay, may arouse the officials to a consciousness of their shortcomings. While sanitary progress has been great, as shown in a reduction of the mortality from 69 per mille before 1857 to 15 per mille at present, many problems are still urgent, as may be gathered from Dr. Harvey's Presidential Address in the Proceedings of the Indian Medical Congress. That typhoid fever can be called the "scourge of India," and that the incidence of the disease should remain so high among the troops, points to serious sanitary defects as yet unremedied. As to the prevalence of venereal disease among the soldiers, an admission of nearly 500 per mille tells its own tale. On reading the journals and discussions one gets the impression that things are not as they should be in India. There seems to be an absence of proper standards of authority. Had there been in each Presidency during the past twenty years well-equipped Government laboratories in charge of able men, well trained in modern methods, the contributions to our knowledge of epidemic diseases might have been epoch-making, and, at any rate, we should have been spared the crudeness which is evident in some of the work (particularly in that upon malaria) of zealous but badly trained men.

THE FUTURE OF MEDICINE IN GREATER BRITAIN.

In estimating the progress of medicine in the countries comprising Greater Britain, the future rather than the present should be in our minds. The strides which have been taken during the past twenty years are a strong warrant that we have entered upon a period of exceptional development. When I see what has been accomplished in this city in the short space of time since I left I can scarcely credit my eyes. The reality exceeds the utmost desires of my dreams. The awakening of the profession in the United States to a consciousness of their responsibilities and opportunities has caused unparalleled changes, which have given an impetus to medical work which has already borne a rich harvest. Within two hundred years who can say where the intellectual center of the Anglo-Saxon race will be? The mother country herself has only become an intellectual nation of the first rank within a period altogether too short to justify a prediction that she has reached the zenith. She will probably reverse the history of Hellos, in which the mental superiority was at first with the colonies. At the end of the next century ardent old-world students may come to this side, "as o'er a brook," seeking inspiration from great masters, perhaps in this very city; or the current may turn toward the schools of the great nations of the South. Under new and previously unkown conditions the Africander, the Australian, or the New Zealander may reach a development before which even the "glory that was Greece" may pale. Visionary as this may appear, it is not one whit more improbable today than would have been a prophecy made in 1797 that such a gathering as the present would be possible within a century on the banks of the St. Lawrence.

Meanwhile to the throbbing vitality of modern medicine the two great meetings held this month, in lands so widely distant, bear eloquent testimony. Free, cosmopolitan, no longer hampered by the dogmas of schools, we may feel a just pride in a profession almost totally emancipated from the bondage of error and prejudice. Distinction of race, nationality, color and creed are unknown within the portals of the temple of Æsculapius. Dare we dream that this harmony and cohesion so rapidly developing in medicine, obliterating the strongest lines of division, knowing no tie of loyalty but loyalty to truth—dare we hope, I say, that in the wider range of human affairs a similar solidarity might ultimately be reached? Who can say that the forges of Time will weld no links between man and man stronger than those of religion or of country? Some son of Beor, touched with a prophetic vision, piercing the clouds which now veil the eternal sunshine of the mountain top; some spectator of all time and all existence (to use Plato's expression) might see in this gathering of men of one blood and one tongue a gleam of hope for the future, of hope, at any rate, that the great race, so dominant on the earth today, may progress in the bonds of peace—a faint glimmer, perhaps, of the larger hope of humanity of the day wh "the common sense of most [illegible] a f [illegible] world in aw

But these, I fear, are the dreams of the closest student who knows not the world nor its ways. There remains for us, Greater Britons, of whatsoever land, the bounden duty to cherish the best traditions of our fathers, and particularly of the men who gave to British medicine its most distinctive features; of the men, too, who found for us the light and liberty of Greek thought—Linacre, Harvey and Sydenham—those "ancient founts of inspiration," and models for all time in literature, science and practice.

SOME DEFORMITIES OF THE CHEST IN THE LIGHT OF ITS ANCESTRY AND GROWTH.

Presented in the Section on Practice of Medicine at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY WOODS HUTCHINSON, A.M., M.D.
PROFESSOR OF COMPARATIVE PATHOLOGY, UNIVERSITY OF BUFFALO.
BUFFALO, N. Y.

I can invite your attention to only a limited portion of the most interesting field of deformities of the chest; and even here my presentation can not claim to be exhaustive, but simply suggestive of certain lines for future work and discussion. The deformities I have chosen are the common and important ones of (so-called) flat chest, "pigeon-breast," "guttered" sternum, Harrison's groove and "funnel chest" ("Trichter Brust"). These may be, at first sight, divided into two apparently distinct classes, those in which the transverse diameter is increased at the expense of the anteroposterior, which for the sake of brevity in our future discussion we will call the transverse or "bellows" form of chest, and those in which the increase appears to be the antero-posterior diameter and the contraction in the transverse, which again, for the sake of brevity, we will call the antero-posterior or "keeled" type of chest. It is also obvious that these increases and diminutions of the diameters are relative rather than absolute, and that when we say that a chest is flattened, what we mean is not so much that its anteroposterior diameter is absolutely diminished, as that this is short in comparison with or relative to the transverse diameter, and *vice versa* in regard to the anteroposterior chest. In fact, the deformities of the chest would appear to depend upon a flattening or compression in the anteroposterior diameter and bulging in the transverse, or *vice versa*. In the transverse or "bellows" class of chests, we would place the innumerable varieties of flat chest, hollow chest as it is often termed, and the singular funnel chest; while under the anteroposterior type would be placed the pigeon breast and guttered, or grooved, sternum. It would also appear that these two divisions corresponded fairly accurately to the two great types of chest among the mammalia. The one, the typical quadrupedal chest—as found in the carnivora, the ungulates, and the great majority of the families of this class—has an anteroposterior diameter which is distinctly in excess of the transverse, so that a transverse section of the chest cavity would form an oval or heart-shaped figure with its long diameter perpendicular to the anterior wall (sagittal). This form of chest is obviously necessitated by and correlated with the backward and forward swing of the anterior limbs in the movements of locomotion. Maximum depth with a minimum width, so far as this may be consistent with abundance of room for the heart and great vessels, is the *desideratum*. This type of chest has passed into popular literature as the well-known "deep" chest of the hound or the race horse; and it is very curious to note to what an extent, by a process of transference, terms which are descriptive of this form of chest have been applied to the human torso, where we shall see they are anything but appropriate. The other type of chest is that in which the transverse diameter equals or exceeds the anteroposterior, and is found almost solely in two widely separate families, the numerous but aberrant order of bats, and the higher primates, the anthropoid apes and man. So striking was this departure from the commonest type that the bats were actually placed in close relation to man, in the old Linnean system. Here again, however, a mechanical explanation would appear to be adequate to account for the form. The two families have absolutely nothing in common, save the fact that the anterior limbs are no longer used for supporting the body during ground locomotion, in the bats being used for flight, and in the anthropoid and human species for swinging through the branches. Thus there is no longer a necessity for a limited backward and forward movement of the limbs in parallel lines, so that the "keel" or boat-shaped form of chest is no longer a necessity, and the great sheet of the pectoral muscles, using the wing in the one case and the hand with the branch it has seized, in the other, as its fixed point, is continually pulling the prominent sternum back toward the vertebral column. The ribs yield at their angle and we have the anteroposterior chest gradually transforming itself into the tranverse form. The bird, it may be said in passing, solves the problem in a somewhat different way by the development of his enormous keel or crest on the sternum, the actual chest wall itself remaining, however, in very much the same shape, with only a slight preponderance of the anteroposterior over the transverse diameter. After the upright position has been attained this modification goes still further. The arms hang by the sides instead of being permanently extended in a forward or dorsiventral direction. The shoulder-girdle, with its great mass of muscles and attached limbs, sinks downward from its former position and begins to press more or less firmly upon the lateral aspects of the chest wall, and the first joint of the limb lies parallel and in contact with almost the entire lateral border of the chest. As a result the lateral expansion of the wings of the chest, which is the chief factor in quadrupedal respiration, as can be shown in the heaving flanks of the race horse or of the hound after the chase, this lateral expansion is interfered with by the pressure and the presence of a joint of the limb in this situation; and the anterior aspect of the chest, having been completely freed from the former splint-like action of the limbs, begins to become the most freely movable part of the wall, and we have the rising and falling or anteroposterior type of respiration to a large extent substituted for the lateral or wing-like type. To afford still greater freedom for this the girdle and its scapulæ recede still further toward the vertebral column until they come, ultimately, to lie almost directly on the flattened posterior wall of the chest. In fact, the chest comes to act like a pair of bellows, of which the vertebral wall is the fixed and the sternal wall the movable flap. I am convinced that one of the most important factors in the proper respiratory development and capacity of the human chest is the extent to which the scapulæ come to lie upon the posterior wall or fixed flap of the bellows.

But I think I hear some one say, "what has all this purely morphologic process to do with us as physicians? Even if it be granted that the human chest, in the course of its development from an earlier quadrupedal form, has passed through these various stages from the keeled to the bellows type, what has this to do with our study of the human chest in the nineteenth century?" Much in every way, and I hope to be able to prove in regard to the deformities mentioned, everything in fact, for the reason that not merely do the probabilities point strongly to our human chest having passed through such stages ancestrally, but every individual chest passes through a number of these stages under our very eyes. In the embryo at the fourth month we have a chest which is almost identical in type with that of the quadruped—the dog, for instance, in which the anteroposterior diameter is as three to two, although it seldom reaches this figure in the embryo. Morris simply gives it as "greater." Macallister says, "the chest is deeper sagitally than transversely." At birth the diameters have come up to the proportion of the lower apes, in which they are almost equal, while from this period up to the twelfth or thirteenth year and to the twenty-fifth even, there is a gradual, steady modification of the chest shape until the full adult "bellows" form is reached, in which the diameters are exactly reversed, viz., as two to three in favor of the transverse. Although, according to Rotch, the proportion is as high as 1 to 2.5 or 3 (D. Powell). Though these changes in proportions are matters of common knowledge and are given in most of our anatomic works, I have been unable to find the exact records upon which the statements are based, and it had been my intention to have included in this paper at least fifteen or twenty measurements of chest diameters at each age at various periods from birth to maturity. but in this undertaking I was unfortunately thwarted and am able to give only the few following measurements and diagrams based upon them, which I think may be taken as fairly typical.

As will be seen by these measurements there is a steady progressive modification of the nearly circular or barrel-shaped chest at birth, up to the transversely oval-shaped chest of adult life. And now the question arises, is this transformation always complete? In my personal opinion it is not, by any means; and I claim that by the arrest of this progress at some particular stage, and exaggeration by the processes of respiration of the proportions which are normal at this particular time, the majority of the special deformities of the chest to which I have alluded are produced. Let us take, first of all, the condition of "pigeon breast.". None of the authorities or theories attempt to shed any light on the crucial question of the whole situation, viz., why a chest which is normally widest in its transverse diameter should suddenly begin to flatten in this diameter and increase in the opposite one. When, however, we look at the question in the light of this change of shape which is taking place, then we can at once see that pigeon breast is simply persistence or a mechanical exaggeration of the normal ancestral and fetal anteroposterior or "keeled" chest. This change or deformity usually begins during the first six to eighteen months of infant life, when the chest is, in the normal child, of nearly equal diameters, and hence capable of elongating with equal ease in either one of them if pressure is brought to bear on it in that direction. In some cases, however, it begins later, when the chest has begun to assume more nearly its adult form, and in this case we have not only a mechanical cause to consider, but also the question whether we have not what might be termed a line of least resistance, which is here, as everywhere, in the direction of the ancestral type. But supposing we have, as is usually the case, a chest whose diameters are nearly equal, or even with the transverse slightly in excess (although it must be remembered that in children who are subjects of pigeon breast there is usually a general backwardness of development in the formation of the skeleton, and it is not improbable that in many cases we have actually a persistence of fetal type after birth, so that the anteroposterior diameter is excessive to begin with), what influence is there which will cause the drawing together of the lateral walls and the forward protrusion of the sternum? In the first place a small amount of influence in this regard may be exercised by the so-called accessory muscles of respiration, the sternal group, all of which tend to pull the sternum upward and slightly forward. But the influence of these is comparatively slight in normal respiration, and would probably be more than overbalanced by the opposite tendency on the part of the intercostal, which are weaker and thinner toward the sternal end of the interspaces, and lacking over the region of the sternum. In fact, there is only one factor which we believe is adequate to account for this singular distortion, and that is the great muscle sheet of the diaphragm. I shall not weary you with anatomico-mechanical descriptions of the origin, insertion and methods of action of this muscle, further than simply to remind you that it is a great fan-shaped sheet which, in respiration, curves up over the roof of the abdominal cavity in a high vaulted dome, which dome, by the contraction particularly of the great crura, is sharply flattened and pulled down, and also flattened from side to side by the lateral fibers; the vertebral column and the inner surface of the lower ribs, acting respectively as fixed points in this descent. That the diaphragm is chiefly concerned in the production of this deformity is admitted by all, and a variety of explanations have been offered to account for its excessive and extraordinary action, chiefly in the direction of obstructions to the entrance of air into the chest in the form of enlarged tonsils, adenoids in the pharynx or obstructions in the nasal passages. The real interference with its action is, however, at the other end of the scale, and comes not from above but below. Normally the diaphragm uses the ribs and vertebral column as its fixed point and pulls down the arch of its center, but when the vault of this center is firmly supported and fixed by a mass of abdominal contents, distended by gas, engorged by portal blood or packed with a mass of enlarged lymphatics, then the action of the muscle is reversed as to its lateral wings and the center becomes the fixed point and the ribs the point acted on. In other words, given a swollen, edematous, abdominal mass and you have the diaphragm at every respiration pulling the lateral chest walls inward and upward, instead of using them as a fixed point to pull its center downward and forward; and this swollen abdomen, which in its extreme form gives rise to the familiar "pot-belly" of poorly nourished children, is precisely the condition of affairs which we find in the majority of cases of pigeon breast. This pressure is exercised almost solely in the transverse direction for the reason that between the vaulted center and the sternum there are no muscular fibers, but only the central tendon, while the muscular masses running from the central to the vertebral column slope downward so rapidly as to cause a protrusion of the abdomen instead of a sinking of the sternum. This explanation will also account for the frequent association of this condition with struma and rickets, in both of which this swollen and distended condition of the abdomen is extremely apt to occur, while in the latter there is also an abnormal softness of the bones to render them still more liable to distortion.

Now, will this relation of affairs account for any other of these conditions? For instance, the well known but not so common "hour-glass chest" with its Harrison's groove, as it is termed. At first sight it would not appear to do so, for the situation of the groove is somewhat peculiar, not at the level of the costal attachment of the diaphragm, but about two interspaces above, in fact, from one to two interspaces below the nipple. First of all, however, let us observe that this groove or constriction is not so much a diminution of the diameter of the chest above this point, as it is a line at which the chest wall suddenly begins to flare outward, and that we are really dealing with a chest of fairly uniform caliber down to this point, but of a sudden and marked widening beyond it. In a few cases, however, the constriction is not merely relative, but absolute as well. As I said, the situation of the groove at first view does not appear to fit in with our theory; but if we will examine a little more closely just what the direction of the tension of the normal diaphragm is, we shall be able to give at least a plausible explanation of how it is produced. The pull of the diaphragm on the lower ribs, when its center is fixed, is not directly inward but inward and upward. Now, what will be the result of traction in these directions acting on a yielding and movable framework like the walls of the chest? Obviously, that the lower ribs having but little or distant attachment to the sternum, would be glided upward and inward *en masse*, until they meet the resistance of the more firmly attached sternal or true ribs above them. When this takes place their further progress will be abruptly stopped, and the pull still continuing, they will, as it were, rotate round this fixed point of the sixth or seventh interspace as upon an axis and, instead of sliding upward and inward, begin to flare upward and outward. Consequently, we would expect to find Harrison's groove occurring in children in whom this marked abdomal distension did not develop until after some degree of rigidity and some approach to the adult form had begun to be attained by the chest, and this will be found to fit with the clinical facts of the case. When once the "flare" has begun it will be exaggerated both by the pressure of the distended abdomen below and also by the tension of the intercostals, and to some extent by the lower fibers of the pectorals and serrati above.

In that rare and extraordinary condition known as "funnel-chest," we have a condition in which the lower end of the sternum in general, and the base of the ensiform in particular, forms the bottom of a deep funnel-shaped depression around which the thoracic walls bulge out above and the abdominal walls below. This is a much more complicated state of affairs, and in the light of our present knowledge difficult of explanation; but we believe that the principal factor will be found to be a firm attachment, by tendinous bands, of this portion of the sternum which is accordingly prevented from yielding in the anteroposterior direction, while the walls of the chest above it and at the sides are bulging forward under the tremendous lateral pressure of the wings of the diaphragm. In other words, I believe it to be, if we may use the expression, a pigeon breast in which the lower end of the sternum has been firmly bound down and prevented from yielding in harmony with the rest of the chest wall. The same explanation will also apply, and much more obviously, to the condition of "guttered" sternum. Here we have a chest which upon measurement will be found to be distinctly above the normal in its anteroposterior diameter, but in which the greatest projection is not in the median line, but in a line drawn parallel with it upon each side about two inches from it. When we come to examine what that line represents, we find that it corresponds to the sternal end of the costal cartilages, and is paralleled by a groove corresponding to the costal ends, the weakest and most yielding point in the entire chest wall of the child; and we have here simply a pigeon-breast in which sufficient tension is exercised by this central tendon of the diaphragm upon the lower end of the sternum to prevent that bone from moving forward freely *en masse*, and consequently the lateral tension of the diaphragm is expanded upon the line of least resistance, which happens to be a double one, and corresponds to the sternal end of the costal cartilages. The curious one-sided bulgings of this description may also be explained in the same way, on the ground that the nutrition of the costal cartilages on the one side was inferior to that of the other. Again the importance of rickets as a producing cause of this disease is self-evident.

So far we have been considering exaggerations of the ancestral chest form, and now we come to those really much more common developments which are implied by the terms flat-chest, hollow-chest, etc., where we are confronted by the adult or human type. I have long been skeptical as to the actual existence of this particular type of deformity, and I regret that I have been unable to make anything like an adequate series of measurements to justify it. But the more carefully one inspects chests of this class, the more one is struck with the extent to which this flattening is apparent and not real. In the first place, even in popular terminology "flat-chestedness" is almost invariably associated with "round" shoulders. In other words, the flattening of the anterior aspect of the chest is in very large measure due to the forward movement and carrying of the great muscular masses of the shoulder girdles. Our standard of flatness or fulness of chest is simply a line drawn across it from one acromion process to the other, and it is obvious that we may have a distinct flattening of this line with a decided round chest, provided that the shoulders have slid forward far enough. As is already suggested in the term round-shouldered, even a mere glance at the hollow chest will show us that a very large proportion of this anterior flattening is due to the gliding forward of the scapulæ and their attachments so that the posterior outline of the upper part of the chest wall, instead of being almost a straight line as it should in the ideal position, is a very decided curve. And upon the application of accurate methods of measurements we find ourselves confronted by the surprising situation that our so-called flat chest is really, if anything, slightly above the normal in its anteroposterior diameter, as is shown by the following all too scanty and desultory figures:

How is this extraordinary optical illusion brought about? Not only is there no inconsistency between the facts, but one is necessarily a consequence of the other. My attention was first called to this relation in examining the chests of some school children who were undergoing special gymnastic exercise for the purpose of overcoming round-shoulderedness. The appearance of the youngsters was characteristic; the chest was flat, the back and shoulders bowed or rounded, the arms swinging slightly in front of the median line in a characteristically anthropoid position. Upon taking hold of the children by the shoulders from behind, and gently but firmly pulling the shoulders backward, while the spine was supported by the knee, it was found that an apparently normal shape of chest could be produced; but the difficulty was that the shoulders would not stay in this position, and a little further experimentation and some measurements revealed that the chest was so nearly round that the scapulæ had no flat posterior surface to rest upon, but were continually sliding forward upon the barrel-like outline of the outer surface of the ribs. This tendency was assisted by the somewhat slouching or anthropoid attitude which boys are apt to assume, and by the contraction of the great pectoral muscles. So marked was this latter fact that, in the language of their gymnasium teacher, they were said to be "muscle-bound," and I found upon inquiry that the trainer was quite familiar with this condition of affairs, and recognized it as a frequent factor in the production of this type of chest and shoulder. In short, the round chest, from the very insecurity of the position which it affords to the inner aspect of the scapulæ, tends to become, under the influence of gravitation and dominant muscle action, the apparently flat chest. In the case of children it is an amusing coincidence that when I asked the trainer what forms of exercise were found to be most useful in correcting this defect, I was immediately told that all sorts of climbing exercises, especially those which were done with the back toward the ladder, rope or framework which was being climbed were most useful. In other words, by a reversion to the arboreal habits of our ancestors who had this form of chest, its progress into the higher form can be expedited. I am not prepared to say that all forms of flat chest will be found to be of this variety, but neither, on the other hand, would I be willing to admit the existence of a flat chest in which the anteroposterior diameter was actually below the normal proportion to the transverse, until more accurate measurements than I have been able to find have been made. There may be and probably are absolutely as well as apparently flat chests, but no measurements which I have been able to discover have proved that fact yet.

Here the objection may very fairly be raised to this view of the matter, why, if these various forms of chests are either reversions to or the exaggerations of the form which prevailed in our healthy, vigorous animal ancestors, should they be associated with lack of vigor, malnutrition and ineffectiveness in the human species? I will conclude by briefly answering this objection. First of all, here as elsewhere, a reversion to a type which was perfectly normal and healthful in some of our ancestral stages may prove to be anything but that under the changed circumstances, as, for instance, the uric acid reversion in gout and lithemia, the molluscan reversion in calcareous, and the sponge reversion in fibroid degeneration. In fact, by the substitution of an anteroposterior bellows-action in the human chest, by the changed position of the shoulder masses and their appendages, the flat chest has become the type of vigor. A moment's consideration will show the reason of this. Placing a bellows in a parallel position, or in the same relative position as the walls of the human chest, with its fixed side held posteriorly and its nozzle upward, it is easy to see that the possible distension of that chest depends upon the range in an upward and forward direction permitted to the anterior flap. Now, supposing that this anterior flap has to be lifted not from a force acting from below as in the case of the hand, but by a force which radiates toward the nozzle of the bellows, it will then be obvious that the further the anterior flap of the bellows is lifted away from the posterior, the less will be the range which it can be caused to travel; or the same point may be illustrated by the bellows itself, when we have the range limited by the leather flaps, the further the free handle is lifted from the fixed, and the shorter the distance which it is capable of traveling. The same thing may be more clearly seen by studying the positions of the ribs and their movements. The ribs slant downward and forward in their natural position, and the capacity of the chest is increased by lifting them up into a horizontal position. It being impossible for them to pass the horizontal position on account of the shoulder-girdle, it is obvious that the more nearly they are forced into this position in rest, the smaller the range through which they are capable of traveling; so the pigeon-breast of rickets, and the barrel-chest of emphysema, are alike rigid chests with very small power of changing their respiratory capacity. This condition is strikingly illustrated in some cases of hunchback in which the chest wall becomes pushed upward and forward into an almost horizontal plane, as was the condition in a case which I examined during the past winter. The result was that the ribs being permanently fixed in the condition of full respiration the chest could be neither enlarged nor diminished by the chest muscles, and the breathing was almost solely abdominal. This rigidity of the chest as the concomitant of pulmonary tuberculosis was long ago pointed out by that acute and brilliant clinician, Fothergill; and the few measurements which I am able to append show with singular uniformity that this rigid chest is also a distinctly quadrupedal or keeled one.

And now for the brief series of measurements that I have as yet been able to make, for valued assistance in the collection of which I am indebted to Drs. N. G. Russell and H. G Matzinger and also to the latter for the diagrams.

My first series was a short one, of patients and members of staff at the Buffalo General Hospital. My second another from the Military Hospital (patients and assistants) at Fort Porter. Last and most valuable a series of fifty soldiers from the garrison at Fort Porter for which as well as the permission for the former, I am indebted to the kindness of Major A. H. Appel, who also appended the ages, weight and height of the men. The results may be thus summarized:

NORMAL CHEST MEASUREMENT. INCHES.
ENLISTED MEN. FORT PORTER.

My measurements were as follows:

1. Length of chest from center of clavicle to lowest point of cartilage of tenth rib, a nearly vertical line on an inch outside of the nipple. 2. Anteroposterior (sagittal) diameter of chest from upper border of sternum (notch) to spine of opposite dorsal vertebra. 3. Anteroposterior diameter (sternum to dorsal spine horizontally opposite) at a line drawn through the nipples (fourth costal cartilage). 4. Transverse diameter at the same line. 5. Anteroposterior diameter at tip of ensiform cartilage. 6. Transverse diameter at same level. From these two indices, like the cranial indices, are constructed, the *length index* found by dividing the breadth at the nipples (four) by the length (one) and the *breadth index* found by dividing the anteroposterior diameter at the nipples by the transverse at the same level. Hence, the lower the index the longer and flatter (more bellows-like), respectively, the chest. From these three series the normal indices would appear to be length index, 85.5, breadth index 72.5.

I believe these figures will not be changed more than 1 or 2 per cent., for all these series agree very closely and the enlisted men have all passed a most rigid physical examination and are of such splendid physique that it is a pleasure to see them strip. Every one of them might be described as "certified normal."

The next table is a series of fetal, infantile and child measurements in which can be clearly traced a more or less regular transition from a high, round, short chest of quadrupedal breadth index to the flattened and slightly elongated chest of adult human form.

From this table we find the following "trial figures:" Fetal breadth index, 103; infantile breadth index (3 years and under), 87; child breadth Index 3 years and over (abnormal), 90; adult, 72.5.

As to flat-chestedness, I have made measurements of seventeen patients selected at random, from the hospital wards for their flat-chested appearance, most of them being tubercular, with the result of an average breadth index of 80 (normal 72.5). In other words all these flat-chested cases were found to have chests on an average 7.5 degrees rounder or "deeper" than the average. In only three cases was the chest flatter than the normal.

Last of all I have to present measurements of some twenty cases of pulmonary tuberculosis in all stages which, though few in number, are a surprisingly uniform series and so far as they go, fully support the contention that the typical tubercular chest is *not* a flat one, but a *round*, *long*, rigid chest. It may be termed, with grim appropriateness, the "coffin chest."

Average Indices								77 3	77
Indices of short series (Tubercular) Erie Co. Hospital . .								82 6	79
General average "Tubercular" Indices								79.9	78

All chests in which there was emphysema or reasonable suspicion of it, were omitted. The indices were: Tubercular patients (19), length 79.9, breadth 78; normal individuals, length 85.5, breadth 72.5. In other words, the consumptive chest appears to be nearly 6 degrees both longer and rounder (deeper) than the normal, so that persistence of the fetal rounded or keeled type with a further reversion to the elongated ancestral type (both of which as already explained impair the efficiency in the erect position) would appear to co-exist at least with a predisposition to phthisis. If this is sustained by more extended measurements it will furnish a most valuable indication for climbing exercises and outdoor life in the chest measurements of children and young adults.

When we remember, in this connection, that the lung in the consumptive is really slightly *more* voluminous than normal, and that, as I have elsewhere suggested, the predilection of the tubercle bacillus for the lung is due to the ancestral recentness of the latter, constituting it the point of least sterility and resistance in the entire organism, it will be seen that the importance of this method of study is likely to be great. If it will help us to detect even a possible predisposition before the bacillus has gained a foothold it will bring us face to face with the hopeful and promising problem of prevention, instead of the discouraging and difficult one of cure. A month of tree climbing may be found worth a gallon of tuberculin.

PHARMACOLOGY OF STROPHANTHUS.

Presented in the Section on Materia Medica, Pharmacy and Therapeutics at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY E. MARK HOUGHTON, M.D.
LECTURER ON EXPERIMENTAL PHARMACOLOGY, DETROIT COLLEGE OF MEDICINE.
DETROIT, MICH.

To Professor Fraser, more than to any one else, belongs the honor of having brought this drug to the notice of the medical profession, and for having determined in a general way its pharmacology and clinical value. I shall not discuss the botany, chemistry or therapeutics of the drug, as these questions have been treated in an appropriate manner by others. I have verified nearly all the important points made in this paper by experiments on animals, using for this purpose freshly isolated strophanthin, and 5 per cent. tinctures, tested by pharmacologic methods, prepared from drugs bought on the open market as strophanthus kombé. The strophanthin from this source is as active as the best strophanthin procurable, and more so than the majority of samples, which vary greatly in strength. Indeed, it was nearly one hundred times as strong as one lot which I examined, and which was claimed to be a chemically pure article.

In general, strophanthus, or rather the active constituent strophanthin, is primarily a nerve and muscle poison, which affects the functions of the various tissues of the animal body in a special manner, in therapeutic doses slowing the pulse, lengthening the systole and diastole, increasing the blood pressure, and the efficiency of the cardiac muscle; and in toxic doses producing rapid paralysis of the heart.

Gley has shown that the local anesthetic action of strophanthin when brought in contact with the conjunctiva is about ten times as great as that of cocain, and that it persists much longer. Steinbaugh, from a long series of experiments on men and animals, concluded that this anesthetic action is not due to strophanthin, but to some other constituent which, when in a pure state, does not cause irritation or produce unpleasant after-effects. Hare and de Schweinitz, in attempting to confirm this work, concluded that Steinbaugh was mistaken and that the substance he used in his experiments was in reality strophanthin, which these authors declare to be a very dangerous drug in ophthalmic practice, since its application may be followed by inflammation and sometimes by ulceration.

Fraser, Boyd, Rovighi and others, claim that strophanthin has an antipyretic effect on patients suffering from various diseases. Martin found the reverse. My experiments on dogs show that a slight lowering of temperature may be produced in normal animals. These investigators also report that the drug is a true cerebral sedative. Their observations were made upon patients suffering from various diseases, and upon animals. In my studies sleep was one of the most constant symptoms noted in dogs, rabbits and guinea pigs under full doses of the drug. Brunton, Baubeyer, Evans and others claim that strophanthus does not have a cumulative action when given for a long time. I have found that if very large doses are given to animals on successive days the second or third dose may be fatal. Especially is this true with rabbits, but generally doses very much greater than should ever be given for therapeutic purposes are well borne by dogs for a number of weeks in succession. In some instances the system becomes more tolerant, as noted by Fraser.

Strophanthus is locally irritating and stimulating to the gastro-intestinal mucous membrane (Wood). It, however, produces much less disturbance to the stomach than does digitalis; in fact some authors claim that therapeutic doses act as a mild stomachic. Clinical experience shows that in many cases strophanthus can be given where digitalis is contraindicated on account of the nausea and vomiting produced.

Strophanthus causes paralysis of striped and unstriped muscular tissue. The quickness with which this result is attained depends upon the concentration of the solution employed.

Like the other members of the digitalis series, strophanthus stops the frog's heart in systole, whether administered subcutaneously or locally. At first the pulsations become slower and more powerful; then the contraction changes to a peristaltic movement, the ventricles dilate less and less, and finally the ventricular cavity is completely obliterated, even when strong efforts are put forth by the auricles to expel their contents. Soon the auricles also cease to beat. This change occurs even when the inhibitory mechanism has been paralyzed by atropin; therefore, it must be due mainly to the action of the drug upon the muscular fibers themselves. The Strassburg school claim that the systolic condition is due to increased elasticity of the muscle fibers. The work of Roy, however, has thrown considerable doubt on this point, while Cushny thinks the ultimate systolic condition is probably due to increased contractility. The whole question is far from settled at the present time.

Since strophanthus is generally used in the treatment of diseases of the circulation, a consideration of its action on the heart and blood vessels of animals is of chief importance. The normal circulation of the animal body, with its many variations that may influence the blood supply to this or that particular organ, is maintained mainly by the action of the heart and the muscular fibers of the arterioles under the influence of the central nervous system, which in turn is regulated by the different afferent impulses or direct influences reaching it. To understand the action of strophanthus upon these factors is to rationalize its therapeutic employment in those cases where the organism is suffering because of some pathologic condition of its vascular mechanism.

Pharmacologists are very well agreed that digitalis, strophanthus, lily of the valley, and the other members of the group have the same qualitative action upon the circulation, but the quantitative relation of the various drugs of the series to the different physiologic factors has been only partially worked out. Most of the work has been done on strophanthus and digitalis. When these various quantitative relations have been settled we shall be able to apply one or another of these remedies, as the case may be, with the greatest certainty according to the pathologic conditions presented in the patient.

A careful study of the papers of the early experimenters on digitalis shows that section of the vagus does not entirely prevent slowing of the heart, but if atropin be given the rhythm becomes normal; consequently the decreased pulse rate when therapeutic doses are employed is mainly due to the stimulation of the vagus centers, and partially to irritation of the peripheral endings of the vagus in the heart. Considerable dispute has arisen as to whether the behavior of the vagus be not due simply to the increased supply of blood to its medullary centers, but it seems to be well established that the drug has a direct action on these centers.

Brunton and others claim that the quickening of the pulse in the second stage is caused by paralysis of the vagus ends, while Schmiedeberg, Cushny and Boehn have shown that it is probably due mainly to the increased irritability of the muscular fibers of the heart. Generally with the slowing of the rhythm the most constant result noted is the increase in blood pressure; but this does not always occur, especially where there is extreme slowing. Brunton and many others regard the increase in pressure after administration of digitalis as due mainly to the constricting action of this drug upon the peripheral circulation, but confess that strophanthus does not narrow the caliber of the arterioles.

Fraser found, by perfusion experiments with strophanthus, that exceedingly large doses of the drug are required to produce even transient constriction of the vessels. Popper claims that with strophanthus the vessels are redder than before. Delsaux, Bradford and Philipps found that the volume of the kidney remains unchanged when studied with the oncometer.

My experiments on various animals convince me that no constriction of the vessels is produced by therapeutic doses of strophanthus. The increased blood pressure must be due mainly to direct action upon the heart.

Popper claims that venous pressure falls as the arterial pressure rises. Little experimental work has been done to prove this point.

Popper and Knoll find that the blood pressure has less influence on the pulmonary circulation than on the systemic circulation. Gley found that curare does not alter the action of strophanthus on the blood pressure, which consequently does not depend on changes in respiration.

Rolleston claims that the maximum pressure in the left ventricle and the output of the heart are increased and the circulation quickened by strophanthin.

Roy and Adami found that strophanthus at first increased the force and efficiency of the papillary muscles, with only slight effect on the walls of the ventricles; large doses quickly paralyze these muscles, having less action on the ventricular walls. Dissociated contractions of the ventricles and auricles occur before this final paralysis.

The recent exhaustive paper of Cushny on the digitalis series has very largely cleared up the question of the relations of increased muscular irritability and central peripheral vagus action. He employed the myocardiagraph, which records the relative distance between two points on the heart, and the cardiometer, which measures the volume of the heart at successive stages, and consequently registers the amount of blood ejected by this organ. These two instruments were of the form devised by Roy and Adami. Cushny divides the action of the drug into: 1. The vagus stage, which is characterized by the results of the vagus stimulation and the direct action on the heart muscle itself. 2. The periodic stage, which begins with acceleration of the ventricles. He examined the movements of the four chambers independently, and also determined their relation to each other when under the influence of strophanthus, employing the myocardiagraph. When small quantities of the drug are administered intravenously there is marked slowing of the rhythm of the heart, the ventricle dilates more fully, and systole is more perfect. The sequence of these changes is not always the same. The slowing and increased contraction are the most constant manifestations noted. Cushny agrees with Ackerman that the former is due to inhibitory action of the vagus, and claims that the increased dilatation is also due to inhibition. Neither slowing nor dilatation occurs when atropin is administered, but this substance has no influence on the increased contractility, which must consequently be due to the action of strophanthus on the muscle fibers themselves.

Without atropin the rhythm is decreased, diastole and systole are more pronounced, and the blood pressure is raised. Tracings taken on fast moving drums show the same, also that the slowing is mainly due to the lengthened diastole, although the pause in systole is somewhat greater. The slowing and increased diastole are the same as when the vagus is stimulated. The time of the relaxations and contractions remains the same as before in the normal animal.

The muscular action of strophanthus is the same on the auricle as on the ventricle, but is less apparent and may be concealed, owing to the greater influence of the vagus, exerting more opposition to the increased muscular irritability. Shortly, if the drug is pushed, what may be called the pause phase begins to manifest itself and the rhythm, which heretofore has been the same in the auricles and ventricles becomes changed. Irregularity and skipped beats may occur in either chamber first, after which the rhythm of the superior and inferior portions of the heart exhibits wide divergence. The systole and diastole become more and more incomplete, until finally considerable pauses are noticed, especially in the auricle. The two sides of the heart after a few intermittent beats begin suddenly, showing a much accelerated rhythm, but the rhythm of the auricles and that of the ventricles is entirely independent, and impulses no longer pass from one to the other.

By careful estimation of the amount of blood passing through the heart as recorded by the cardiometer during the first stage of strophanthus action, Cushny maintains that, "the contraction volume or output of the ventricle per beat is uniformly much increased, whether slowing of the rhythm is marked or not. This is, of course, due to increased systole, augmented in some cases by increased diastole of the ventricles." The amount of blood expelled per unit of time varies according to the amount of slowing produced. Where the rhythm is only slightly lessened the output is increased, but if it is greatly retarded the output is below normal.

This increased work must be due to increased muscular action, since Roy and Adami find that the heart ejects less blood when the vagus is stimulated. The increased dilatation of the ventricles due to vagus stimulation, helps to offset the slowing. If the nervous mechanism is paralyzed with atropin the contraction volume is greater, owing to more perfect systole and the output is *uniformly increased*.

Blood pressure is raised during the first stage, even before a change in the heart is noticed. In general, during the first stage analogous results are shown by the myocardiagraph, cardiometer and kymograph, slowing and increased work; if atropin is used increased work without slowing.

I have dwelt at length on the primary action of strophanthus because it is never desirable to go beyond this stage under any condition in the therapeutic application of the remedy. In fact it is not wise to produce more than a moderate degree of the first stage, as better filling of the vessels is secured when the rhythm is but moderately decreased.

At the close of the first stage, as already mentioned, the ventricular and auricular contractions become slower and slower, and may occasionally skip; soon, however, the irritability of the muscle becomes so much increased that the restraint of the vagus is thrown off and the ventricles usually first, soon followed by the auricles, show an accelerated, very irregular rhythm, the ventricles beating together, and the auricles also having the same rhythm, while the normal sequence of the respective contractions is entirely destroyed. The inhibitory mechanism still acts, but is entirely insufficient to control the exaggerated muscular activity. The individual beats of the different chambers are very irregular and the amount of work is greatly lessened; soon the spasmodic effects of the organ cease, generally in the auricles first, in a position somewhat nearer diastole than systole; then follow delirium cordis and complete dilatation.

Knoll, working with a less perfect myocardiagraph than that devised by Roy and Adami, obtained results which correspond quite accurately with those obtained by Cushny. Neither Cushny nor Knoll has yet completed their observations on the action of the heart during the second stage. During the second stage there is generally present an increased excitability of the central nervous system, and violent movements of the respiratory and other muscles occur, the animal appearing much as though under the influence of one of the convulsive poisons.

It has been found from extensive experiments that diuresis is one of the most constant results noted when strophanthus is administered to healthy individuals (Semoine) or to patients suffering from various cardiac lesions (Fraser, Semoine, Wood and others). The diuresis may be due entirely to increased blood pressure, to direct renal action (Wood), or to a combination of the two. The action of strophanthus is very much more rapid, and the drug is eliminated from the system more quickly than is the case of digitalis, presumably because of the greater solubility of its active constituent strophanthin, which is probably excreted in the urine (Wood).

During the past two years with a view of ultimately being able to standardize all the various preparations of the digitalis and strophanthus series by physiologic methods—since they can not be assayed by chemic means—I have examined hundreds of samples of crude drug and active constituents, as purchased on the open market or procured from private sources. The task is indeed a difficult one, owing to the small amount of quantative work that has been done. Sufficient data have already accumulated to convince me that the task of perfecting pharmacologic methods for standardizing all those powerful drugs and chemicals which can not be assayed by other methods is not a hopeless one. Owing to the ready solubility of strophanthin, the preparations of strophanthus are perhaps the most easily standardized of the heart tonics.

As already stated the strophanthin on the market varies greatly in strength. The same is true of the crude drug. As physicians, I believe the time has come when we should demand at least a qualitative pharmacologic examination of these drugs before they are made up into pills, tablets, tinctures, fluid extracts, etc.

The sphygmographic work of Fraser, Paschkis, Zerner and especially Wilcox, shows that strophanthus produces the same effects on the circulatory apparatus of man as upon that of other mammals. The fatal dose of strophanthus varies for different groups of animals. Reusing and others claim that strophanthus is at least twenty times as strong as digitalis. Fraser claims it is 300 times as strong. I have found one sample of strophanthin sufficiently powerful to kill medium-sized frogs in doses of 1-7000 of a grain. For therapeutic use I believe 1-300 to 1-200 grain of strophanthin, and from 3 to 5 drops of a 5 per cent. tincture to be the correct dose.

Briefly summarizing the pharmacology of strophanthus we may say that its chief action is upon the nervous mechanism controlling the action of the heart, and upon the heart muscle itself, lessening pulse rate, increasing the blood pressure and augmenting the work of the heart; without causing constriction of the arterioles or any special action on the vasomotor mechanism; the diuresis and other important results being due mainly to improved circulation.

Its special advantages over digitalis may be briefly stated as follows: It does not produce gastric disturbances, and does not show cumulative action. The constriction of the vessels by digitalis may be a source of great danger owing to the extra strain thrown on the ventricle, especially in fatty heart. Strophanthus has no such tendency. It acts quicker and with greater certainty. Owing to its ready solubility it is better for hypodermatic administration, and the strength of its preparations can be more easily standardized.

Let us have a Department of Public Health!

STROPHANTHUS; A CLINICAL STUDY.

Presented in the Section on Materia Medica, Pharmacy and Therapeutics at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY REYNOLD W. WILCOX, M.D., LL.D.
PROFESSOR OF MEDICINE AND THERAPEUTICS AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; PHYSICIAN TO ST. MARK'S HOSPITAL.
NEW YORK CITY.

For many years I have been convinced that the very discordant reports made by competent observers were due to the fact that the source of strophanthus preparations was varied, for otherwise it would be impossible to believe that excellent effects could be obtained from one preparation while another would give rise to alarming or even dangerous symtoms. And further it is impossible to believe that the very large doses so frequently mentioned in literature could be safely administered, if the preparation had been made from an active crude drug.

Last January, I read a paper before the Medical Society of the State of New York which was published in the May number of the *American Journal of the Medical Sciences* giving the results of a careful study of strophanthus kombé. In this paper I stated that I believed that kombé was not a variety of strophanthus hispidus, but a distinct species. In that study based on extended observation of twelve patients I made use of a tincture prepared according to the terms of the "United States Pharmacopeia," and standardized by physiologic methods, reaching the following conclusions: That success in the administration of strophanthus requires; an active well-made preparation from a reliable source; avoidance of its use in fully or overcompensated hearts, or in those which present advanced muscular degeneration or mechanical defects of high degree; the use of not too large nor too frequently repeated doses.

From these observations it was apparent that a dose of five drops of this preparation, three or possibly four times a day, is sufficient. From this preparation of strophanthus kombé (pubescent variety), we could discover in a short time that the line of ascent of the tracing of the pulse as taken with the Dudgeon sphygmograph became longer and more perpendicular, the distance, between the successive apices longer, the dicrotic wave disappearing, while the irregularities were almost always overcome. In other words, under the influence of this preparation the force of the heart beat became stronger, its rate slower and its rhythm more regular. This change took place without any change in blood tension other than could be justly attributed to a more powerfully and evenly acting heart. Coincident with these changes in the pulse there were also equally well-marked changes in the pitch, volume and quality of the heart sounds, clearly indicating that the heart was working under a better mechanical advantage. With all these changes as determined by physical signs, the patient would note the relief of breathlessness, the diminution of pain, the disappearance of swelling, the increased flow of urine, the improved appetite, and the disappearance of palpitation or, if the last did not disappear, fluttering was changed to more forcible apex beats. These conclusions are, I believe, fairly presented and justly based on the observations recorded in the above mentioned paper.

As I have said above, the study was made of a single preparation from a single drug source. It is my purpose now to give you the results of my observations on other preparations from other drug sources. Early in March of this year I received, from Dr. H. H. Rusby, fluid extracts made from different species of strophanthus. The following are the observations:

A.—Fluid extract of strophanthus hispidus, from No. 16 powder containing 1.815 per cent. of strophanthin.

Case 1.—This was administered to a woman aged 35 years who, on March 14, complained of constent dyspnea, swelling of feet, severe chest pains, and palpitation. Physical examination showed moderate aortic obstruction, marked mitral incompetency, slight mitral obstruction, with long standing myocarditis. The dose was five drops in a wine-glass of water after meals. The following is the pulse tracing.

March 28. The patient announces that the breathlessness and palpitation are relieved but the medicine causes four or five watery, rather painful movements. The dose is reduced to four drops.

April 7. The patient has now no swelling of the feet but still complains of the diarrhea. The dose is now reduced to two drops.

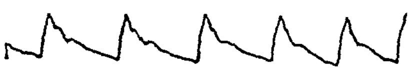
April 21. The patient has complained of some nausea, but the symptoms of the cardiac lesion have become less; however, it is thought best to abandon the use of the drug.

B.—Fluid extract of strophanthus hispidus from No. 30 powder containing 1.726 per cent. of strophanthin.

Case 2.—April 1. A young woman 26 years of age has been troubled with palpitation and pain in the heart on exertion: she had noticed an enlargement of the neck for the past four months. Physical examination revealed a simple goiter, mitral incompetency and dilatation of the left ventricle. The patient received four drops of this preparation.

April 7. The palpitation has been somewhat less severe and the pain has diminished. The goiter is slightly softer.

April 17. The patient complains that the medicine nauseates and requests its discontinuance.



Case 3.—A woman aged 55 years, very obese, has suffered from swelling of the feet, palpitation and dyspnea for about two years. Physical examination revealed mitral insufficiency with considerable dilatation of the left ventricle and presumably a fatty degeneration. Two drops were given thrice daily on April 2.

April 9. The symptoms are slightly relieved.

April 16. There is considerable improvement in the dyspnea and the edema has disappeared.

April 23. The palpitation is still marked but less than formerly. As the improvement is not sufficiently great and the patient complains of the griping and diarrhea the medicine is omitted. (See E.)

Case 4.—A woman 64 years of age has been breathless for many years particularly on exertion. She was thin, active but tired easily. Examination showed considerable mitral obstruction and incompetency with slight aortic obstruction. The muscular wall of the ventricle is in fair condition. Three drops were ordered thrice daily on April 23.

May 9. The patient has observed considerable caution in her movements and feels stronger.

May 16. She does not tire so easily, but complains of loss of appetite.

May 23. The shortness of breath is markedly better, but some nausea has appeared.

C.—Fluid extract of strophanthus kombé (pubescent variety) from No. 30 powder containing 3.372 per cent. of strophanthin.

Case 5.—On March 24 a woman 55 years old presented herself complaining of fainting sensations on exertion, extreme nervousness and mental depression. She was found to have thickened aortic valves and a dilated left ventricle. Three drops, thrice daily were ordered.

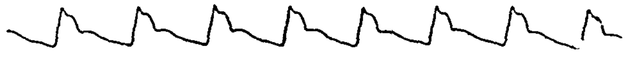
March 31. There has been no return of the fainting sensations.

April 7. The mental depression is less but the appetite is poor.

April 14. On account of the loss of appetite the amount of the drug is diminished to two drops. The nervousness is less.

April 21. In spite of the diminished dosage, diarrhea is now complained of and some abdominal pain.

April 28. The digestive symptoms are still annoying.



Case 6.—A rather stout but active woman of 60 complained of swollen hands and feet, headaches, dyspnea and oppression on exertion. Examination showed insufficiency of the mitral valve, ventricular dilatation, possibly fatty infiltration. Two drops of the preparation were given thrice daily on March 28.

April 7. The edema has become considerably less.

April 9. An attack of vomiting with purging commenced today, and medicine is now omitted.

April 14. The strophanthus is now resumed, the digestive symptoms having been attributed to dietary indiscretion. The edema has returned.

April 21. The headaches and oppression are relieved; the edema is less.

April 28. Nausea has appeared for all that the symptoms of cardiac debility are less.

Case 7.—On March 31 a woman aged 41 years applied for relief from persistent headaches, palpitation and precordial distress on exertion, from which she had suffered for many years. Examination showed some aortic regurgitation with marked mitral obstruction and less apparent regurgitation. She received four drops thrice daily.

April 2. The headaches are lessened in severity, but the palpitation is persistent.

April 7. The precordial distress appears only on severe exertion.

April 9. Headaches have been absent since last report, but the appetite has become seriously impaired.

April 16. The patient complains of loss of appetite, but admits the improvement in other symptoms.

April 23. There have been two attacks of diarrhea and the condition of the appetite is unchanged. (See I.)

Case 8.—On April 1 a man aged 52 years complained of great breathlessness, fainting sensations, fatigue on slight exer[illegible] which had become gradually worse d[illegible] six m

Examination discovered slight aortic obstruction, marked *mitral incompetency, with* extreme ventricular *dilatation.* Three drops were ordered thrice daily, with rest in bed.

April 5. The dyspnea has improved.

April 9. There have been no fainting sensations since last report.

April 14. The improvement still continues. He may now recline on a sofa during the daytime.

April 16. The patient complains of nausea. The dose is diminished to two drops.

April 22. The nausea has disappeared, but total inappetence has arisen. On two days there has been diarrhea. One drop is to be given thrice daily.

April 26. The condition of the patient has remained unchanged. (See H.)

D.—Fluid extract made from strophanthus kombé (non-pubescent) No. 30 powder containing 1.87 per t. of strophanthin.

ase 9.—A man aged 42 has suffered from gouty attacks for 1 years. He is easily fatigued, suffers from precordial on and pains extending down left arm. He was found to have aortic obstruction, probably secondary to degeneration of the conus arteriosus, with considerable ventricular dilatation. On March 26 he was directed to take five drops thrice *daily.*

April 3. There have been no attacks of pain in the arm.

April 10. The oppression is less marked, but the fecal movements are softer in consistency.

April 17. The strength has improved, but the appetite is impaired. The character of the movements is unchanged.

Case 10.—On March 28 a man aged 31 consulted me for the relief of palpitation, chest pains, slight swelling of the feet and dyspnea on exertion. There was found on examination a fairly well compensated heart, but presenting aortic obstruction and mitral incompetency. Four drops of the preparation *thrice daily were ordered.*

April 7. The edema has entirely disappeared and the pains are slightly better.

April 12. Improvement continues.

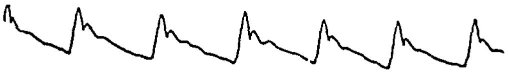
April 19. The dyspnea is considerably improved and the general condition good.

April 26. The improvement is not so marked and but littl progress has been made.

Case 11.—A woman aged 67 consulted me on March 23 fo painful swelling of the feet, cough, headache, restless slee and dyspnea. Examination revealed marked incompetency a both aortic and mitral orifices, with moderate dilatation Three drops were ordered to be administered thrice daily.

April 5. The feet are still swollen, but less painful; th cough has disappeared.

April 19. For all that the headaches, disturbed sleep an shortness of breath are better, a severe attack of diarrhea during the past four days, which was not accompanied by eithe nausea or vomiting, necessitated the omission of the drug.



Case 12.—A woman 48 years of age complained of genera weakness, swollen feet, headache, disturbed sleep and dyspnea Examination showed slight aortic obstruction, with bot incompetence and obstruction at the mitral orifice. There wa slight dilatation. On March 24 three drops were ordere thrice daily.

April 7. The sleep has improved and the feet are les edematous.

April 14. The headache has disappeared, the dyspnea i less and considerable exertion is possible without distress, bu the appetite has been entirely lost. (See F.)

It will be noticed that in nearly all the cases th symptoms which brought the patient to the physicia were relieved; in some they entirely disappeared. O the other hand the investigation had not been long i progress before it was apparent that the preparation were causing digestive disturbances varying from simple inappetence, nausea and vomiting to abdominal pai and diarrhea. Were it simply a question of purgation these untoward symptoms might be disregarde or possibly it might be considered to be beneficial in that it might relieve the edema. Yet on the whole the irritating properties of the fluid extracts as concern the alimentary tract are undesirable and certainly limit their employment within narrow lines. The behavior of the fluid extracts is in marked contrast to that of the tincture, which in none of the twelve cases recorded in my previous paper, created any digestive disturbance.

The following observations were made upon hypodermatic tablets of strophanthin from the same manufacturer as of the fluid extracts.

E.—Hypodermatic tablets, one two-hundredth of a grain each, obtained from a No. 30 powder of strophanthus hispidus which contained 1.726 per cent. of strophanthin.

Case 3.—(See above.) On April 25 the patient was directed to take by the mouth one tablet dissolved in a teaspoonful of water before each meal.

May 2. There are at present no intestinal symptoms.

May 9. The palpitation is much improved and the dyspnea is entirely relieved.

May 16. The patient presents an excellent appearance and the cardiac sounds are distinctly stronger.

F.—Hypodermatic tablets, one two-hundredth of a grain each, from No. 30 powder of pubescent strophanthus kombé containing 3.372 per cent. of strophanthin.

Case 12.—(See above.) One tablet is given as above, commencing April 17. During the three days' abstinence from medicine the appetite has been regained.

May 13. The swelling of the feet has entirely disappeared, the sleep is tranquil and the patient expresses herself as greatly improved.

G.—Hypodermatic tablets of one two-hundredth of a grain from No. 30 powder of non-pubescent strophanthus kombé containing 1.87 per cent. of strophanthin.

Case 13.—On April 4 a woman aged 56 years complained of weakness, headaches, palpitation and precordial distress, the last two symptoms being especially marked on exertion. On physical examination there was found marked mitral insufficiency, slight aortic obstruction (vegetations) with marked dilatation of the left ventricle.

April 10. The patient feels stronger and suffers less from headaches.

May 3. The palpitation had improved and the distress is less upon exertion.

May 17. The appetite and bowels are in excellent condition and there is general betterment.

May 24. The patient feels much stronger and had not suffered from headache since last report.

H.—Hypodermatic tablets of strophanthin, one two-hundred and fiftieth of a grain each, from strophanthus kombé (pubescent variety).

Case 8.—(See above.) On May 6 one tablet was directed to be taken dissolved in a teaspoonful of water before each meal. The diarrhea and inappetence had disappeared.

May 9. The dyspnea has markedly improved.

May 12. The patient now sits up the greater portion of the day.

May 15. There has been a great gain in strength.

May 19. The dyspnea has entirely disappeared and moderate exertion is possible without fatigue.

Case 14.—A woman of 60 has been unable to walk without fatigue for several years. She also complained of swollen feet, fainting, dizziness, pain in left side of chest and a persistent cough. Examination on May 6 revealed a well-marked incompetency of the mitral orifice and extreme dilatation of the left ventricle. One tablet was ordered to be given as above.

May 20. The cough, dizziness and edema have diminished and the pain in the side has disappeared. This instance is notable for the rapidity of relief.

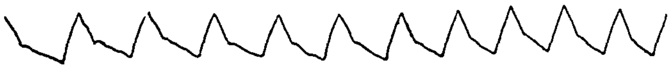
I.—Hypodermatic tablets of one three-hundred and fiftieth of a grain from strophanthus kombé (pubescent variety).

Case 7—(See above.) On May 6 the patient reported that there had been no further attacks of diarrhea and the appetite had returned.

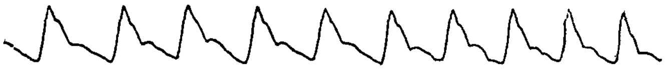
May 8. The patient feels stronger.

May 10. The palpitation is markedly improved and distress is no longer felt.

May 14. The heart sounds are distinctly more vigorous and the general improvement continues.



May 21. There has been no palpitation since the last report and the cardiac first sound is improved in quality, pitch and intensity.



Case 15.—A man aged 25 years consulted me with reference to persistent headaches, general weakness, excessive nervousness and palpitation. Physical examination on May 9 showed mitral incompetency with slight dilatation of left ventricle. One tablet was given as above.

May 15. The palpitation is lessened and the patient is less nervous.

May 22. There has been no headaches nor palpitation since last report. The patient feels markedly stronger and can endure less fatigue.

Case 16.—A woman aged 26 years had suffered from fainting, dizziness, headaches, and palpitation for three months. Examination revealed an anemia and probably a secondary dilatation of left ventricle with consequent mitral incompetency. On May 14 she was directed to take one tablet as above.

May 21. Although this report covers but one week yet there is distinct improvement as regards fainting, headaches and palpitation. The anemia is not appreciably changed, although the cardiac first sound is distinctly stronger.

On studying the histories of these patients it will be observed that there was no digestive disturbances produced by the tablets; this is marked contrast to the results of the administration of the fluid extracts. It will be further observed that in the case of the three first mentioned tablets that the source was the same as of the last three fluid extracts.

From my observations we may fairly conclude: 1. The tincture of strophanthus kombé (pubescent variety) is an active and eligible preparation of which the maximum dose should be five drops four times daily. Of the tinctures made from strophanthus hispidus, which are found in the shops many are inert or nearly so. 3. The fluid extracts of strophanthus hispidus and of strophanthus kombé (both varieties) are unsuitable preparations on account of the digestive disturbances which they occasion, and these appear to be independent of the amount of strophanthin contained in the crude drug. It is likely that the character of the preparation is responsible for these untoward effects and possibly it may be so changed that these objections will be removed. 3. The hypodermatic tablets of strophanthin as prepared from all kinds of strophanthus and are satisfactory preparations in dose of from 1-350 to 1-200 grain, and are not irritating to the digestive tract. The source of the glucosid, and the strophanthin percentage of the crude drug are apparently without influence on their activity. The reputation which strophanthus enjoys, of being an irritant drug is probably based on the use of the fluid extracts.

These tablets do not, so far as limited experience indicates, irritate when used hypodermatically and the smaller dose (1-350 gr.) seems to be sufficient for all practical purposes.

I had hoped to be able to report on the clinical use of strophanthus bracteatus, but have not been able owing to failure to obtain a supply of the crude drug. If I might base an opinion on the excellent researches of Boinet it is likely to prove to be an irritant to the alimentary tract and in spite of its demonstrated action upon cardiac muscular fiber, it is probable that its clinical use would of necessity be marked by caution in administration.

This paper has been written in the hope that the profession may learn to carefully determine the mechanical problems which present themselves in the treatment of cardiac diseases and meet the indications with scientific precision. The advantages of approved preparations of strophanthus over digitalis are: 1. Greater rapidity of action. 2. Absence of so-called cumulative effects. 3. Non-interference with the caliber of the arteries. On the first point it can be truly said that reliance on digitalis for the emergencies which may occur in surgical cases is absolutely without a scientific basis. On the second the fact that digitalis has ceased to be quite as harmful, as it might be helpful, only since the practice has become general to combine it with a nitrite is sufficient reason for the use of strophanthus. And lastly the marked safety of strophanthus in the aged, nephritic, gouty and atheromatous, as well as the fact that it should be the cardiac remedy for children, needs no argument for the search for reliable preparations. The reputation of strophanthus has suffered in the past from the variability, unsuitability and unreliability of the commercial preparations. That is now removed and we know the dose and the preparation on which we may rely. I ask for the drug the same careful study and observation which has been accorded to digitalis, and I doubt not that a just verdict will be reached within as many years as decades elapsed before digitalis came into scientific employment.

749 Madison Avenue.

DISCUSSION.

Professor REMINGTON of Philadelphia—We are undoubtedly reaching a point where the relations of pharmacy and general medicine are coming closer and closer. I can not discuss the physiologic action of the drug; but I may discuss some of its physical and chemic qualities, and the difficulties which he had in making preparations of the remedy. I understood Prof. Wilcox to say that from the use of the fluid extract of the drug he obtained untoward results; but that from other preparations, such as the tincture or the glucosid itself he did not obtain these unpleasant effects. Now reasoning from analogy it is quite probable that the fatty material in the crude drug may be responsible for these effects. Fraser, in his experiments, extracted this before using. If this were done it might be that the fluid extracts would then become eligible preparations.

Dr. J. C. HEMMETER of Baltimore—It is well to have clear cut ideas in our study of the physiologic action of drugs, for the reason that there are many organs in the body which are affected contemporaneously. The action must be limited to the organ which we are studying. The observations of the German experimenters is open to the objection that they do not confine their observations to single organs. In Prof. Wilcox's paper we had a study directed to one question, does strophanthus act as a stimulant to the heart muscle or through its effect on the blood vessels? I may recall some experiments which I made with digitalis when a student with Dr. H. Newell Martin in the laboratory of Johns Hopkins University, in order to determine the effects on the heart. The heart of a frog was isolated from all surrounding structures, including nerves and blood vessels. The heart was then placed on a warm stage, and connected with two reservoirs of defibrinated blood, in one of which the medicament was placed. By this means we could study the effect on the heart tissues by comparing its action when the pure blood was supplied with its action when the digitalis was introduced. These experiments were repeated too often and studied too closely to admit of error; they forced us to the conclusion that after the administration of digitalis the effects on the heart are due not to any action upon the wall of the heart, *but entirely to its influence upon the nerves* and blood vessels. This was followed by another line of experiment to study the action upon the blood vessels. In this experiment the mesentery of the living frog was placed on the stage of the microscope and immersed in warm salt solution, so as to keep the stage wet during observation. It was noticed that as soon as the drug was introduced into the circulation, there was a contraction of the blood vessels like that observed after administering ergot. I merely mention this to show the importance of confining our observations to one organ in studying the effects of a remedy.

Prof. Wilcox—I would be remiss in my duty if I did not record my appreciation of the value of the work which Dr. E. M. Houghton of Detroit has done and also my gratification that the results of laboratory investigation confirm the observations made in clinical medicine. I may say with regard to the suggestion of Professor Remington that the tincture furnished by Parke, Davis & Co. is satisfactory and no bad results follow its use, whereas the official tincture is unsatisfactory because of great variations in strength. I desire particularly to call attention to the necessity of having these preparations standardized. The crude drug varies in their percentage of strophanthin from 1.726 to 3.372, so that, according to their source, they should not only be standardized by chemic means but also by physiologic methods, if we wish to get good results from their use. *Finally, I call attention to one other point:* Before you get the full effect of digitalis when administered by the mouth, some forty-eight hours must elapse; but you can get the same results at once from the hypodermatic injection of one two-hundred and fortieth of a grain of strophanthin in about twenty minutes because of the great solubility of the latter.

Dr. E. M. Houghton of Detroit—Before this investigation is complete, a very large amount of work must be done before we decide upon all the factors which must be taken into consideration in establishing the physiologic effects of strophanthus. I trust that during the coming year this work will be carried on and I will endeavor to do my part, especially in the line of physiologic investigation.

OBSERVATIONS IN THE USE OF DIPHTHERIA ANTITOXIN, WITH SPECIAL REFERENCE TO ITS USE IN MALIGNANT CASES.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa., June 1-4, 1897.

BY ALEXANDER McALISTER, M.D.

CAMDEN, N.J.

In bringing this subject before you it is my purpose to confine myself to those features of the disease which demonstrate the rationale of the serum treatment, as now recommended by all leading clinicians.

The development of the bacillus of Löffler in a susceptible individual constitutes diphtheria in its primary form. The seat of development, a local lesion, is usually the mucous surface of the respiratory tract, but may be any mucous surface or flesh wound of the body. The medium of infection is atmospheric air, and the portions of the body most exposed are the tonsils because of their structure, function and situation. It is important in this connection to recall the anatomy of the tonsils. They are racemose glands, covered with reduplications of the oral mucous membrane. Their inner surface presents from twelve to fifteen orifices leading into small recesses, from which numerous follicles branch out into the substance of the gland. The orifices, recesses and follicles are lined with a continuation of the pharyngeal mucous membrane. The viscid secretions which serve as a lubricant invite to the folds of the tonsils the diphtheria bacillus; when once within these folds in a susceptible person, they not only rapidly develop, but in so doing produce toxins of most astounding virulence. In their development *per se*, they constitute the local lesion of diphtheria; as their toxic products are absorbed and carried by the circulation to every part of the system they produce indirectly the constitutional lesion of diphtheria. The pseudomembrane is always present and more or less extensive, but this does not constitute the essential lesion. The latter is the acute degenerative cell change particularly affecting the mucous membrane underlying the local lesion, but showing a marked predilection for the cardiac muscles, the kidneys, the peripheral nervous system and the lymphatic glands. In necropsies of malignant cases this cell destruction is shown in extensive localized necroses in these organs.

Diphtheria is a self-limited disease which tends toward a fatal issue. For reasons which are not now fully understood, the rapidity with which symptoms appear and the membrane spreads, or the course of the disease is run after infection, varies considerably in different persons. Next to the importance of an early diagnosis stands the question of malignancy. Formerly a malignant case of diphtheria was one that terminated fatally; but with the advent of our present superior methods of the serum treatment many cases once properly so classed recover. Malignancy now refers to the severity of a case rather than to its termination, depending on the seat and extent of the pseudomembrane and the virulency of the infection.

While the former may be ascertained by inspection we have as yet no means of knowing the latter in advance of its dire effects. The virulency of diphtheria toxins is nowhere more forcefully demonstrated than in a case of the disease in which a comparatively small number of bacilli situated in a mere speck of pseudomembrane produce a high degree of toxemia almost from the first. In such cases the bacilli of the infection are especially virulent and determine the malignancy of the resulting disease. In cases attended by extensive formation of pseudomembrane the malignancy of the disease is due to the rapidity of absorption of toxins from the local lesion or to the mechanical impediment they cause to the respiratory function. The rapidity of absorption on the other hand, depends on the particular understructure of the affected membrane. In laryngeal diphtheria the pseudomembrane is often quite extensive, yet because of the underlying membrane it is not so tough as elsewhere, and the absorption of the *toxins and the resulting toxemia do* not form an element of danger. On the other hand, because of the structure of the larynx and trachea and their abundant nerve supply, the immediate danger is from stenosis, spasm, cyanosis and asphyxia. Such cases show comparatively little *toxemia and are generally* not followed by the usual sequelæ. Glandular enlargement, albuminuria and sthenic symptoms are wanting, and in necropsies of cases that die early, localized areas of parenchymatous degeneration in the heart and kidneys are not observed.

The opposite, however, is true where the local lesion is situated on the pharyngeal mucous membrane. Here the resisting basement membrane is displaced by glandular structure, vascular sinuses, erectile tissue and the like, and absorption takes place very rapidly. A fibrous network is situated around and among the above structures, and connects the mucous membrane to the periosteum. The glands are composed of tortuous tubules with many sinuses and oblong offshoots, all favoring rapid absorption. This applies especially to the rhinopharynx and nares where the hypersecretion which attends all acute inflammations of these parts makes the field all the more favorable to the thrifty development of the bacillus of Löffler. Vascular engorgement and accumulation of nasal secretions alike facilitate, the one in the formation of a specially dense membrane and the other in making the colony of bacilli specially thrifty. Such cases run a comparatively short acute course, and if they do not terminate fatally are followed by a train of sequelæ and attended by complications.

Barring any immediate danger from asphyxia, which is now readily met by intubation, the highest consideration in the question of treatment should always be the nature and degree of toxemia present. The danger now confronting the serum treatment of diphtheria, greater than any other, is that it be applied generally upon an empirical basis. To obviate this it is of importance that the question of malignancy and the degree of toxemia of each case be carefully studied. A scientific remedy requires to be employed scientifically. In a certain sense each case is a law unto itself. It is not sufficient to say that antitoxin must be administered during the first two, three or four days of the disease. It is possible that any case may speedily change in type and prove fatal within twenty-four hours. At times a case will run this short course when the pseudomembrane has the most innocent appearance and occupies only one or two recesses of a tonsil. If the infection could be early recognized and treated in its incipiency, nothing in the remedial art would be easier than the cure of every case of diphtheria with one moderate dose of antitoxin. But cases must be treated as they are found, and alas, many are not found until the disease has made serious inroads by damaging vital organs or arousing latent disease. "The prognosis of any case of diphtheria is always doubtful, since the mildest case may become severe and the severe may improve. The prognosis is especially grave among children and in proportion to their youth; sucklings, however, are rarely affected. The progress is more severe among patients debilitated by previous disease or faulty hygienic surroundings. The outlook in the individual is worse as the disease becomes sceptic or gangrenous, since mixed infection there exists." (Wood's "Practice of Medicine," 1897, fol. 172)

In my own practice I have found it advantageous to distinguish between early and late cases in the question of dosage and supplementary treatment. This is not based on an estimate of the hours or days the disease has probably continued, but on the progress it has made. Though somewhat arbitrary, it seems to me the best classification that can be made for the purpose. A thorough clinical examination of the patient will generally suffice to determine to which class a particular case belongs.

Early cases will require only the initial dose of antitoxin, 1,000 units. The disease is promptly arrested and its natural course cut short. In such cases the patient is generally found quite well on the third or fourth day, and no sequelæ or complications will be observed. The conditions found are as nearly those of experimental diphtheria as is possible in clinical practice and accordingly the full specific powers of the remedy are obtained. In a series of early cases the physician's work becomes a matter of simple routine. He administers the requisite dose of antitoxin, orders a mild aperient and directs that the nose and throat be kept clean with a mild antiseptic or alkalin. Other remedies are not needed, and frequently it is difficult to keep the little patient in bed. If one will review his work as compared with his experience in the disease before the introduction of antitoxin, he is tempted to pronounce such cases of mild type and probably so conclude that many of the cases would have recovered without specific treatment. Bearing in mind, however, the gravity of any diphtheritic infection and the natural tendency of the disease, it is safe to declare that of a given number of cases treated with antitoxin early, less than 1 per cent. would have terminated in complete recovery within four days if treated otherwise; while according to the best pre-antitoxin statistics, between 25 and 30 per cent. would have died. On the other hand the 70 to 75 per cent. that would have recovered would have run courses ranging from ten days to three weeks and been attended by both sequelæ and complications. This applies to all cases treated early whether the type of the disease is pharyngeal or laryngeal. Cases treated early with antitoxin are universally mild because treated early; and remain mild because treated scientifically and specifically.

Late cases usually require more than one dose of antitoxin. The conditions to be met are graver and less easily appreciated than in early cases. In addition to the primary lesion there is the secondary or constitutional lesion. The pathologic condition from being purely local has become widely disseminated throughout many and important organs of the body. The toxins absorbed from the pseudomembrane have caused the essential lesion of the disease or scattered centers of cell necrosis. From these centers arises a new element of danger. The way in which this is caused is clearly indicated in the following from Louis Fisher: "If large quantities of this so-called membrane-toxin are absorbed into the system through neglected or delayed treatment, these toxins transform the albuminoid bodies of the tissues and cause tissue poisons or tissue toxins. These tissue toxins can be classed as those that belong to digested proteids, and those that are not proteid substances. The first is an albumose; the second is an organic acid. Albumoses have a specific action on the human organism; when present in large quantities they produce fever, and if allowed to act for any length of time they produce paralysis. In very large quantities they produce great exhaustion and also fatty degeneration of the heart and kidneys. It is in these cases that antitoxin at times fail, owing to the presence of poisons other than those peculiar to pseudomembrane, and which are by-products of degenerative changes in the tissues."

In late cases then the condition is that of primary diphtheria for which antitoxin is fully specific, plus the damage already done and its grave constitutional results. The cases seen late are frequently of mixed infection, streptococci or other pathogenic organisms having followed upon the diphtheritic infection.

The local lesion soon becomes gangrenous and the constitutional condition, that of approaching pyemia. To this must be added in a certain percentage of cases the effects of pre-existing disease, either manifest or latent. While it is now largely conceded that antitoxin exerts specific power in neutralizing the membrane toxins and arresting the primary infecting process, it is not known to have such action against the tissue toxins, and certainly will not restore the integrity of damaged organs. In these cases the danger from the disease *per se*, is not so great as that from the damage already sustained by vital organs. The former is much more promptly amenable to treatment than the latter.

In treatment every feature must be kept in view. As early as possible the primary infecting process must be removed. It is impossible to form an adequate estimate of the number of antitoxic units required to accomplish this. The symptoms hyperemia, stupor, coma, or certain physical signs, the appearance, condition and extent of the pseudomembrane, the rapidity of spread may indicate a high degree of toxemia and mark the case as one of great malignancy, but all these form no basis for estimation. The condition must be met by special dosage. In these severe cases give 2,000 units of antitoxin and repeat the dose in eight to ten hours if the desired effects are not obtained. The full neutralizing effects of a dose of antitoxin are secured on absorption of the serum and within ten hours. To wait a longer time before repeating the dose is to expose the tissues of the body to further damage from the unneutralized toxins. Too much importance can not be attached to the use of concentrated serum. The smaller bulk is more promptly absorbed and results can be confidently expected in a much shorter time than when weak serums are employed. When this rule is followed I find comparatively few late cases require more than two doses. Late cases are always to be regarded as in imminent danger. Any undue effort or excitement on the part of the patient may induce cardiac paralysis. The patient's strength must be husbanded by quiet, the recumbent posture and nutritious food. To tax the heart as little as possible I have the foot of the bed slightly elevated. To these measures must be added, in many cases, cardiac and general tonics and stimulants. Such cases always run a more prolonged course and are often attended by complications and sequelæ. Though the disease proper is cured by the entire removal of the primary infecting process, the damage already sustained is sufficient to carry the disease process through a fixed course with the above named results.

Since introducing the serum treatment of diphtheria into my practice in January, 1895, I have employed it in sixty cases with a loss of five. In all these cases, excepting a few seen in consultation with other physicians, the diagnosis was confirmed by laboratory culture. They embrace all types and all degrees of malignancy and include a number of cases seen quite late in the disease. My earliest experience was with the French product, but since a most excellent antitoxin has been furnished by a reliable Philadelphia firm I have used this exclusively. My first eighteen cases were treated in the West Jersey Orphanage and all recovered. These have been under my observation ever since and are in perfect health to this day. My results with the treatment have been entirely satisfactory in every particular, so that my former dread of meeting diphtheria cases has entirely left me. My only anxiety now is to see the cases reasonably early.

When I hear a physician question the value of antitoxin in the prevention and cure of diphtheria, or what is more in the face of the volume of testimonies now in its favor openly oppose antitoxin, my conclusions are that he has never used it or seen it used; or if the contrary is true, that a reliable product was not employed or was employed improperly. Antitoxin is not employed scientifically when the physician delays in order to first know whether the patient will most likely die without it, or to have his diagnosis confirmed by a culture before inaugurating the serum treatment; or when employed it is given in too small doses and at too long intervals.

STREPTOCOCCIC INFECTION AND MARMOREK'S SERUM.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics at the Forty-eighth Annual Meeting of the American Medical Association held at Philadelphia, June 1-4, 1897.

BY GEO. W. COX, M.D.

CHICAGO.

The study of bacteriology during the past few years has developed many interesting facts, not alone to the scientist, whose labors and interests are confined to the laboratory, but also to the clinician, whose work it is to practically apply the knowledge furnished him by the former. It would be difficult to name any one branch of the subject which could justly claim precedence if viewed merely in its scientific aspect, for all are of absorbing interest in this regard; but in the matter of practical application and tangible results it may be safely asserted that the study of the streptococcus microbe stands first in the list. It is the most widely distributed of any of the members of its class; it is more variable in its morphologic development than any of the others; it is unique in the matter of biologic characteristics, and it is decidedly the most far-reaching in its pathogenic effects. Unlike any of its congeners its mere presence does not signify a single specific operation, but may be the harbinger of one of several conditions that vary widely in their effects on living tissues. Thus the microbe is found alone or associated with other micro-organisms in such diseases as erysipelas, puerperal septicemia, diphtheria, scarlatina, bronchitis, bronchopneumonia, septic wounds, gangrene, salpingitis, otitis, appendicitis and many others, as well as on the mucous surface of the natural orifices of the body in individuals who appear to be free from disease of any kind.

The very fact of the presence of this germ in such a large number of diseases and conditions of dissimilar character makes it difficult to attribute to it any certain and fixed pathology; while on the other hand this seeming confliction of testimony readily accounts for the wide diversity of opinion that exists between various observers as to its nature and effects.

It does not come within the scope of this paper to treat of the history, morphology, biologic characteristics and pathogenesis of this germ, for these are all lucidly taught in various text-books; but rather to deal with the practical side of the question of what to do with the little mischief-maker when we have found it. In passing, however, we may state that it belongs to the facultative anaerobic group—living both in the presence and absence of oxygen—and, according to Sternberg, is a spherical coccus from four-tenths to one micro-millimeter in diameter on the average, but varying considerably in size. It multiplies by binary division, forming chains of various lengths by the adherence of the elements to each other, and making one of the most attractive fields to be seen in the bacterial world. The germ grows readily, but somewhat slowly, in nearly all kinds of media, solid, semi-solid and liquid, and multiplies in temperatures ranging from 16 to 60 degrees C., but most readily between 30 and 37 degrees C. It stains readily with the aniline colors, and also by Gram's method. For the best inspection a magnifying power of about 1000 diameters is required. It shows beautifully under a one-twelfth inch immersion lens.

While we have here a microbe that is easy to cultivate and easy to preserve, it is with much satisfaction that we can confidently assert that it is also easy to destroy. It succumbs to the influence of appropriate treatment with such alacrity that but a few days were required to completely annihilate it in any of the tests that have come under my personal observation.

It may be true that Méry, as mentioned in the *Bulletin Médical* (France), April 22, 1896, isolated a chain microbe from a malarial fever patient which resisted the antistreptococcus serum; but may it not also be true that the serum used for the test was stale, attenuated or otherwise unfit for use? Such instances are so very rare that they should not be permitted to stand against the thousands of successful trials, and be used as an argument against the [illegible]; but should rather be regarded as accidents or the results of faulty experimentation.

It will be noticed that we speak of the streptococcus in the singular number, thereby indicating a belief in the unity of this form of germ. Such is the opinion held by several of the most careful investigators; and while more than a dozen different species of streptococci have been described by various observers, we think it has been quite clearly shown by the researches of Marmorek and Widal that they are all so closely related as to be the offspring of a single parent microbe.

The difference in size, form and effects may be accounted for by the widely different conditions under which they have been cultivated. All have noticed the difference between cultures made in artificial and natural media, and even between those made in natural media of different origin. In the cultivation of the streptococcus it was early noticed that in some instances the chains were long, forming immense and fanciful loops, and exceedingly virulent in character. In others the chains were short, straight and comparatively innocuous, leading to the belief that the virulence was in direct proportion to the length of the chains. This theory, however, was soon exploded, as it was found that by inoculations of the same cultures into rabbits and mice, the resulting chains would be long in the former and short in the latter, while the virulence would remain the same in both. It was these widely varying results, obtained by untiring zeal in the prosecution of innumerable experiments, that led Marmorek to the belief in the unity of the streptococcic germ. In his interesting report of his work in this line, published in the *Annales de l'Institut Pasteur*, July, 1895, he sums up in these words: "Our experience confirms the opinion of those who regard all streptococcic affections of man as due to one sole microbe."

Having settled in his own mind the question of the character of the germ, Marmorek began the task of making a serum for its destruction. In this work every facility was afforded him by Professor Roux, who placed all needed appliances at his disposal, while wise counsel and encouragement were constantly furnished by his old friend and colleague, Dr. Metchnikoff.

Others had been engaged in this work before the young Austrian was ever heard of in the world of science, special importance attaching to the researches of Roger, Behring, Mironoff and Lingelsheim. These investigators succeeded in establishing many points of interest in connection with the development and effects of the germ itself, and even prepared a serum that was partially successful in destroying it. However, they never succeeded in procuring a serum of sufficient potency to effectually act upon the severer forms of the infection. A good and sufficient reason for this failure will be suggested in the following division of this subject, namely:

The serum.—Like all blood serums, antitoxins and products of like character, the antistreptococcus serum requires time, skill and experience for its proper manufacture. A lack of one or more of these factors has undoubtedly led to the production of inferior serums, and consequently to failure and disappointment in their use. It has been clearly demonstrated that "laboratory serums," such as were formerly made by using the usual selection of members of the rodent family are so attenuated as to be almost inert. Such animals do not seem to be able to resist the toxic effect of repeated injections, and hence the serum procured from them is not of sufficient potency to act with much if any effect upon the germs. This seems to have been the difficulty with the serums made by the four pioneer manufacturers already alluded to They deserve all praise for their foresight and for pointing the way which eventually led to such a great achievement by another. Their work was a triumph, but their patience gave out, their enthusiasm abated, their faith relaxed, or for some other reason they abandoned a noble cause and left a half finished task to be completed and gloriously crowned by that indefatigable worker, Alexander Marmorek. This great investigator may be said to have commenced where the others left off. He began to use larger animals in his experiments and at once noticed a decided improvement in the serum. First he utilized the sheep, then the ass and finally the horse, when the ideal seemed to be reached. This animal tolerates the toxin remarkably well and yields by far the largest quantity of serum of any yet tried; hence it is the one now exclusively used by Marmorek in the preparation of his serum. Not only is it necessary to exercise good judgment in the selection of animals, but it is even of greater importance to properly care for them during their treatment, and especially to avoid a too early withdrawal of the blood. The process of manufacture is necessarily a slow one and the utmost patience is required for its accomplishment. Not only must oft repeated injections be made to insure the proper degree of potency, but even after the animal is known to be thoroughly immunized and after the last injection is made several weeks must be allowed to elapse before the blood is withdrawn, as during the reaction the blood is actually toxic and if injected into rabbits during this time will invariably kill them in from five to ten days. On the other hand, if allowed to remain until the reaction has ceased it may be used upon these animals with impunity. This discovery constitutes one of the notable features in the great work of Marmorek, whose enduring patience enabled him to accomplish so much and without which the world would yet be in all probability without an effective and reliable streptococcic remedy.

Marmorek has shown that the serum is effective in exact proportion to the amount of toxin received by the animal. He has also demonstrated that the serum as manufactured by him, although the strongest of any yet made as regards the toxic action on the microbe, is incapable of working injury to the human organism. This feature he attributes to the great care taken in its manufacture. Like all the blood serums made at the Pasteur laboratories in Paris, it is entirely without antiseptics. It is claimed by Roux that his vast experience in the manufacture of antitoxins and serums has taught him that antiseptics can do no possible good and are capable of doing a great deal of harm. The serums are not preserved by the antiseptics, as is popularly supposed; they will only keep a certain length of time; they must be kept at a proper temperature in order to retain their activity, and if so kept, will remain potent as long without antiseptics as with them. Made without antiseptics there is scarcely any limit to the dosage, as the toxic symptoms following injections are always due to these so-called preservatives or other impurities, and not to anything that is inherent in a pure blood serum.

A very conservative and fair-minded editorial appeared in the *Medical News*, April 24, 1897, concerning the uses of this serum, and while the editor rendered a verdict of "not proven" in regard to the various claims made for it, he more than offsets this verdict by his honest admission of what may occur under favorable conditions. He mentions the harmlessness of a pure serum, notes that only one case of kidney involvement has so far been attributed to its use, and admits that no one is in a position to say that the disease itself (septic infection) was not responsible for the renal involvement. He goes on to state that "our apparent lack of success up to the present time may be due to the *imperfect* or *insufficient* administration of the serum." He advises the use of Marmorek's serum in connection with appropriate surgical measures, warning his readers to "utilize a serum obtained from a reliable source and free from extraneous substances, such as carbolic acid," on the ground that such a product is "hardly likely to do harm, and may do a world of good."

Therapy.—By far the most important division of this subject is the one which treats of clinical data. In this we can speak with greater confidence, notwithstanding the fact that we are occasionally confronted by theoretic clashings which tend to make our position at first glance appear somewhat paradoxic. For example, an ordinary acute abscess seems to bear very little resemblance to a case of erysipelas, especially a case of erysipelas in which suppuration does not occur; and yet it is admitted on all hands that the pathogenic germs of these two affections are identical, one being the "streptococcus erysipelatis" of Fehleisen (1883) and the other the "streptococcus pyogenes" described by Rosenbach (1884) and Passet (1885). Again, puerperal septicemia caused by streptococcic infection and chronic inflammation of the middle ear, do not seem to stand in very close relation to each other, and neither of them would ordinarily be placed in the same class with either of the two diseases just mentioned: and yet we have in all of them the same pathogenic force at work, and all of them readily yield to the same line of treatment.

It would be impossible to enumerate all the diseases in which the streptococcus figures, either as the principal or as a complication, for the simple reason that in all probability not a tenth of them are known; but it is sufficient for us to know that wherever and whenever found it is a danger signal of weighty import, and that immediate steps should be taken for its destruction. It is no argument to say that because certain so-called "kinds" or "species" of the germ are harmless we would ever be justified in waiting for a demonstration of their virulence. If the deductions of Widal, Marmorek and others who believe in the unity of the germ are correct, the most benign of them may, by change of conditions, soon become the most virulent.

In order that I may not be misquoted or misunderstood, I wish to distinctly state that the antistreptococcus serum is only recommended for streptococcic infection, and not for diseases or conditions in which this infection does not exist. Some cases of puerperal septicemia are caused by the bacillus coli communis, and in the treatment of these the serum would be without effect. But in the greater number of cases chains of streptococci are found in large numbers, and these yield to the serum treatment in a most remarkable manner. Hence we emphasize the necessity of a bacteriologic examination in every suspected or doubtful case, in order that treatment may be pursued upon rational and scientific lines. As a general rule there is ample time for thus settling the question of diagnosis before treatment is begun; but in occasional instances where the gravity of the case would render delay dangerous we would advise yielding to empiricism to the extent of administering at least one efficient dose of the serum without waiting for the bacteriologic test, knowing that in any event no harm would follow, while, as has frequently been the case, it might be the means of saving a human life.

When we say that erysipelas may be aborted by the use of this remedy, we speak from authority furnished by the case-books of reputable physicians. To say that it can always be aborted would probably be a flagrant error; but that it may always be modified, ameliorated and abridged is the almost universal verdict of the profession of two hemispheres. If its value as a therapeutic agent had to be measured by its power over one such disease as puerperal septicemia, it would doubtless retain its place in the list of valuable remedies for all time to come. But such is not the case. We already have such an overwhelming array of proof of its efficacy in a number of apparently diverse conditions as to lead to the belief that it will soon be esteemed as the most valuable of the blood serums yet discovered. Besides the diseases already mentioned, in which it may be relied on to effect a cure with little or no other treatment, it has been used with remarkable sucess in many cases of mixed infection, removing with great promptness an ugly complication and rendering a disease amenable to ordinary treatment, which would otherwise have resulted fatally. Among such diseases may be mentioned diphtheria, scarlet fever, bronchitis, bronchopneumonia and phthisis pulmonalis. In the last named it has been especially useful, as will appear in the report of cases to follow.

It is claimed by several observers that, no matter what the disease may be, the use of the serum is always followed by increased leucocytosis. If this be true, and the army of fighting phagocytes can be recruited at will, what mind can foretell the future, even the near future, of this infant that we designate sero-therapy? It is already one of the recognized branches of legitimate medicine in the old world, and is rapidly gaining in popularity here. The diphtheria antitoxin is no longer an experiment with us, and considering that the Marmorek serum was only introduced into the United States less than a year ago, its success in this country must be regarded as little less than phenomenal.

Reports of cases.—In France, where the serum has been used most extensively, the weight of evidence is vastly in its favor. True, it has been severely criticised in a few instances, but a careful study of such cases has generally resulted in victory, rather than defeat, for the serum. They have almost invariably been cases of mixed infection in which the serum was expected to exhibit powers not attributed to it by its discoverer, and, very generally too, when it was given in *inadequate doses.* In some instances, too, where adverse opinions were expressed, an admittedly weak or doubtfully prepared serum was used. Thus in the *Botkins* (Russia) *Clinical Gazette,* No. 43, 1896, we find a report of sixteen cases of scarlet fever treated by Dr. L. Rappoport, in all of which a serum was used. This series of cases he divides into three groups, as follows: Four of "medium gravity," two "severe," and ten cases "with various complications." The serum employed was of Russian manufacture, and admitted to be much weaker than Marmorek's; and as [illegible]0 c.c. was the maximum dose given in any one case, it seems but natural that some of the cases should die "without," tó quote Dr. Rappoport, "the serum having had any apparent effect upon their course." Very different from this report is the one of Dr. Rondot, made at the meeting of the French Medical Congress held at Nancy, France, Aug. 6, 1896. In this report Dr. Rondot gives his experience with Marmorek's serum in the treatment of a large number of cases of erysipelas. He invariably found that the serum produced a rapid improvement in the general condition, and marked reduction of temperature and diminution in the duration and gravity of the disease. In the most severe cases there was always rapid and pronounced retrocession in the acuteness of the lesions.

At the meeting of the Ophthalmologic Society of France, Nov 3, 1896, Dr. Boucheron related his successful use of Mamorek's serum in the treatment of purulent dacryocystitis and other cases of streptococcic infection of the eyes. He, in common with Widmark, Morax and others had noticed that many cases of dacryocystitis were caused by the streptococcus, and that they were always of a well defined type. The most rebellious of these are those that he specially commends for the serum treatment. Boucheron also found that this serum could be successfully used as a preventive of streptococcic infection of the ocular organs at the time of operation for cataract or ocular traumatism.

Drs. Vahle, Steffek, Döderlein and Walthard all found the streptococcus present in the vaginal secretions of such a large proportion of pregnant and parturient women that Dr. Vahle arrived at the conclusion that before every accouchement, even in healthy subjects, prophylactic injections of the serum should be made. (*Zeit. für Gebur. und Gynec.*, Vol. 35, No. 2.)

At a meeting of the Medical Scientific Society of Lyons, France, Dr. Vinay reported thirteen cases of puerperal fever treated with Marmorek's serum, nine of which were eminently successful. This is not a record to be ashamed of; but it is highly probable that with more extended experience in the technique of administering the serum since these cases were reported, the percentage of recoveries would be considerably increased in a similar series at this time.

In the London *Practitioner*, April 1897, Mr. Watson Cheyne reports three cases of prophylactic injections of the serum in removal of malignant disease about the tongue and upper part of the pharynx, cases which are so generally followed by septic infection. No such infection followed in any of these cases, two recovering with no unpleasant sequelæ and one dying from cerebral embolism.

The *British Medical Journal*, Oct. 31, 1896, contained a report from Dr. J. I. Williams of fourteen cases of severe puerperal septicemia treated with Marmorek's serum. Twelve (86 per cent.) of these made excellent recoveries, and in the other two it was admitted that treatment had been too long delayed.

Dr. Lainsbury, at Royal Free Hospital, London (*Lancet*, Oct. 10, 1896), reports a case of malignant endocarditis cured by the use of 70 c.c. of the serum, the beginning dose being 20 c.c.

Dr. Sevestre, in charge of the diphtheria patients in the Sick Children's Hospital, Paris, uses Marmorek's serum freely in all cases of mixed infection, with excellent results, the proportion of recoveries being considerably augmented since the employment of this remedy.

M. Cuffer reports a remarkable recovery after the use of twenty-eight vials of the serum extending over a period of one month. The case was one of endocarditis, pericarditis, congestion of the lungs with pleurisy, arthritis and éndometritis. He also reports a case of acute pelvic inflammation in which the left broad ligament was infiltrated forming a very large tumor. Injections of serum prevented the formation of pus in the tumor and all unpleasant symptoms rapidly disappeared.

Dr. Chantemesse of Paris, had remarkable success in the treatment of 411 cases of erysipelas in which he used the serum. In every instance the symptoms were most favorably influenced by the treatment; and after deducting three cases which were absolutely hopeless on account of complications, the recoveries were 99 3 per cent.

But it is not necessary to remain on the other side of the Atlantic in order to find reports favorable to this line of treatment, and I have so far done so principally to show the wide range of application of the serum. Coming home, then, we begin the report of cases by mentioning some that are characterized as "unsuccessful." In this list one of the most interesting is the series of six cases reported by Dr. R. F. Wier at the New York Academy of Medicine, and published in the *Medical Record*, May 1, 1897. Antistreptococcus serum was used in all of the six cases, and according to the report, "with no apparent benefit." According to the *Record*, a brief analysis of these cases is as follows:

Case 1.—Tuberculous ileo-lumbar abscess. On the fifth day after opening *streptococci* and *staphylococci* were found. Serum used. No benefit.

Case 2.—Chronic tubercular ostitis of the femur; after operation *staphylococci* were found, but no *streptococci.* Serum used. No benefit.

Case 3.—Carcinoma of the breast; amputation of the gland. Does not state whether streptococci were found. Serum used. No benefit. Death.

Case 4.—Compound fracture of the femur involving the knee-joint; suppuration; amputation. Serum used. No improvement. The report does not state whether or not streptococci were found.

Case 5.—General extensive purulent peritonitis from appendicitis. Serum used. No benefit. Death. Does not mention the presence or absence of streptococci.

Case 6.—Perforative appendicitis with general suppurative peritonitis. In this case "the only effect of the serum was on the pulse."

It is difficult to understand why six such cases as these should be reported as an argument against antistreptococcus serum. Cases 5 and 6 would almost necessarily terminate fatally under any line of treatment; cases 3 and 4 might reasonably be expected to succumb to the surgical operation and systemic infection, while in case 2 it is admitted that none of the germs (streptococci) were found, for which alone this serum is recommended.

Dr. Lilienthal, in discussing Dr. Wier's paper, mentioned that his experience had been most favorable, and that the eight cases in which he had used the serum had led him to predict a great future for it.

Dr. Van Arsdale, also of New York, reported two interesting cases, one of appendicitis with general purulent peritonitis, and the other gangrene of the gall bladder accompanied by seropurulent peritonitis. Both were extremely grave, but under appropriate surgical measures coupled with the use of the serum, recovered.

Dr. Henry W. Berg of the Willard Parker Hospital, has reported so many instances of the successful use of the serum in cases of diphtheria and scarlatina where there was mixed infection, that his experience must be familiar to most practitioners and it is therefore only necessary to mention it here.

The *Medical Record*, March 14, 1896, and the *Medical News*, April 4, 1896, both give glowing accounts of the efficacy of Marmorek's serum in the complications and sequelæ of scarlet fever. Adenitis, otitis and albuminuria are among the complications mentioned by these authorities, and all of them were speedily controlled by the serum.

Prof. E. E. Montgomery (JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Aug. 1, 1896), advises the early use of the serum in puerperal septicemia in daily doses of 20 c.c.

Dr. Howard Lilienthal (*Medical Record*, March 20, 1897), reports a case of a child supposed to be suffering from rheumatism of the hip joint. The doctor opened an abscess, found chains of streptococci, and used the serum with success.

Dr. Gerster corroborated Dr. Lilienthal and said he had used the serum in a number of cases at Mt. Sinai Hospital, including such diseases as peritonitis, appendicitis and general sepsis, and all with excellent results, some of the recoveries being regarded as marvelous. Dr. Richards in the same journal reports the successful use of the serum in a case of puerperal septicemia in which the prognosis was very bad.

Reasoning from analogy it may be supposed that the gynecologist will find in Marmorek's serum a sheet-anchor in his specialty. He finds pus everywhere. It confronts him in the reproductive tract from the ovary to the ostium vaginæ, and is one of his most dreaded enemies in the connective tissue throughout the pelvic cavity. It can not be possible that all of these are of gonorrheal origin. Many of them must be sequelæ of simple congestions brought about by innocent and unavoidable causes. If Marmorek's serum controls this condition when applied in the congestive stage in other localities, why not also in this hotbed of abscesses? We believe it will do so if intelligently employed, and we believe also that laparotomy, so frequently resorted to in the past may often be rendered unnecessary by this simple and easy means.

In conclusion we will refer to the use of Marmorek's serum in cases of tuberculosis, having purposely reserved mention of this disease till the last on account of its vast importance. A little more than a year ago Dr. Chas. T. McClintock of Ann Arbor read a paper before the Michigan State Medical Society, in which he predicted that the antistreptococcic serum would find its greatest usefulness in cases of tuberculosis. That was the first published utterance to this effect, and Dr. McClintock has proved himself a prophet. During the month of July, 1896, Dr. W. H. Weaver of Chicago used Marmorek's serum in three such cases, reporting them in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Sept. 5, 1896. That was the first published report of cases treated in this way. Since that time a number of cases have been so treated by physicians in different parts of the country, but little or nothing has been published concerning them. Why, it would be difficult to say. The importance of the subject would seem to merit more attention than it has received. In all the published reports, however, and in all received from private sources, there has been a pleasing unanimity in the action of the serum. Without exception it has done all that was expected of it. That is to say, it has invariably destroyed the streptococcus microbe and thus freed the case from a disagreeable and dangerous complication. Having thus converted the case from one of mixed infection into one of simple tuberculosis, the system is left in better condition to resist the ravages of the tubercle bacillus, and consequently more likely to respond to appropriate treatment for the destruction of this germ. The serum should be used in those cases only where the bacteriologic test shows the presence of the streptococcus microbe. In all such cases there is liable to be considerable cough, purulent expectoration, night sweats, high temperature, insomnia and anorexia, all of which are greatly modified and sometimes disappear altogether under the influence of the antistreptococcus serum. Oftentimes the train of symptoms just enumerated will be found where there is no streptococcic infection. These, as a rule, are very grave cases and the serum treatment is not indicated. Lack of space forbids a detailed account of the progress of the different cases in which the serum has been used; but suffice to say that while some of them were hopeless as far as ultimate recovery was concerned, yet without exception there was such decided amelioration of distressing symptoms as to lead to the conclusion that earlier employment of the serum would at least have resulted in greatly prolonging life.

Dosage.—Marmorek's serum should always be used by hypodermic injection into the cellular tissue. If due antiseptic precautions are observed and ordinary skill used in its administration, it is free from danger, and the dose is practically without limit.

In all grave cases, such as puerperal septicemia, and especially if treatment has been considerably delayed, an initial dose of 30 c.c. is advised. This may be followed by doses of 10 c.c. or 20 c.c. every twelve or twenty-four hours, according as the symptoms are affected.

In ordinary cases of erysipelas the initial dose is 20 c.c., and in many instances may be all that is required. However, it may be repeated once or twice in twenty-four hours if necessary. In the complications of diphtheria and scarlet fever one dose of 10 c.c. will be found sufficient in the vast majority of cases. In the mixed infection of tuberculosis, the dose should ordinarily be 10 c.c., to be repeated every second or third day until the microbes have disappeared from the sputum, usually requiring from four to six injections.

In all other affections, such as acute abscesses, pelvic inflammations, chronic inflammation of the middle ear, and in suppurative processes generally where the streptococcus germ is found, the dose must be regulated according to the exigencies of the case.

Children bear the serum remarkably well, and 10 c.c. is the usual dose for children of all ages.

Almost any part of the body where the skin is not tightly drawn may be selected for the injections. In adults preference has usually been given to the lumbar or gluteal regions; while in children the lower abdomen, a little to the right or left of the median line, is more frequently selected. A perfectly sterile syringe and needle should be used; and unless some special condition exists to call for more thorough cleansing, the site may be sufficiently prepared by a careful bathing in alcohol.

Conclusions.—1. In Marmorek's serum we have a remedy of the greatest therapeutic value. 2. So far as known, it is only applicable to streptococcic infection, simple or mixed, hence it naturally follows that, 3. An early bacteriologic examination should be made in order to settle the question of diagnosis and point the treatment. 4. Its action upon the microbe is rapid and certain if given in adequate doses.

2258 Wabash Ave.

DISCUSSION.

Dr. Flagg—I would ask where this serum can be obtained in this country; also whether in order to use it the physician must make bacteriologic examinations and cultures in every case.

Dr. Ames—I was impressed, while listening to this paper, by its possibilities in the treatment of tuberculosis. I would ask whether or not Dr. Cox can refer to any other reports of its use besides his own work in the treatment of tuberculosis? I would suggest that a combination of the nuclein with the streptococcic serum might be suitable in the later stages of tuberculosis.

Dr. Cox—The remedy can be obtained at the agency for the Pasteur Institute (the Pasteur Vaccine Co.) in Chicago. There is no work on the subject that I know of except this communication I have just read.

Dr. Hill—I have been using antistreptococcic serum for some time. I think that an idea, suggested by Dr. Cox, to have an examination made when possible in order to settle the value of the remedy, is a good one. In other words, do not condemn a remedy without being scientific in your treatment. In many cases the laboratory examination is unnecessary, and the clinical diagnosis is quite sufficient. For instance, in erysipelas and in puerperal septicemia, you have a perfect illustration of streptococcus infection. You can not make a mistake in diagnosis. In these cases, it has never failed me.

Dr. Cox—In closing the discussion, I must express my delight at witnessing the interest shown by the members of the Section in the subject of serotherapy. I am glad that I have been able to correct some false impressions growing out of the indiscriminate use of serums of uncertain value. In reply to the question as to the necessity of making bacteriologic tests in every case, it is stated in the paper that this should always be done when practicable, always excepting cases where delays would be dangerous. The experience of the chairman is in keeping with that of other careful observers, viz., the rapid destruction of the streptococcus germs. It is to be hoped that those especially interested in the study of that dread disease, tuberculosis, will be on the lookout for complications caused by this germ and direct their treatment accordingly. I desire to emphasize this request, inasmuch as the subject is of such vital importance to the race.

CLASSIFICATION AND SURGICAL TREATMENT OF ACUTE PERITONITIS.

Read by invitation in the General Session of the International Medical Congress, at Moscow, Russia, Aug. 20, 1897.

BY N. SENN, M.D., Ph.D., LL.D.

CHICAGO, ILL.

(Concluded from page 463.)

Methods of drainage.—At present there are three methods of drainage in general use: 1. Tubular drainage. 2. Capillary drainage. 3. A combination of tubular and capillary drainage. All of these methods have their advocates and are applicable under certain circumstances. No one method of drainage will answer in all cases.

Tubular drainage.—Tubular drainage is specially indicated in cases in which the abdominal cavity contains pus. The tubes employed are made either of glass or soft rubber. Keith's glass drains answer an excellent purpose in draining the lowest portion of the abdominal cavity. They should be slightly curved at the abdominal end so as to reach the floor of the pelvic cavity without making harmful pressure against the bladder. Frequent aspiration of the contents of the drain is necessary for the purpose of removing the fluid inflammatory product as soon as it is formed. The rubber drain answers the same purpose, but is properly accused of causing more mechanical irritation than the smooth glass tube. Prolonged tubular drainage has not infrequently caused intestinal fistula by pressure. It is for this reason that I now almost invariably surround the rubber or glass tube with a few layers of iodoform gauze securely fastened to the tube. In draining the pelvic portion of the abdominal cavity I frequently use two drains the size of the little finger, one on each side brought out through the same opening in the lower angle of the wound. In draining in the lumbar regions and through the vagina rubber drains should be employed.

Capillary drainage.—Capillary drains are frequently employed as substitutes for the tubular drains and in addition must often be relied on as an important hemostatic resource in arresting parenchymatous oozing. Iodoform or sterilized gauze are usually employed as capillary drains in draining the abdominal cavity for peritonitis. Bardenheuer first resorted to strips of iodoform gauze in draining the peritoneal cavity. The greatest objections to this method of drainage are the danger from iodoform poisoning if a considerable quantity of gauze is used, the difficulty of removing the gauze, and the likelihood of a ventral hernia as a legacy. The name of Mikulicz is connected with a special method of gauze drainage of his own device, familiarly known as the Mikulicz iodoform gauze tampon or drain, which has proved of the greatest value in abdominal operations and in the surgical treatment of peritonitis. The typical Mikulicz tampon is made by taking a piece of iodoform gauze the size of a large handkerchief, to the center of which a strong piece of aseptic silk thread is stitched. When used it is arranged as a pouch and is carried by means of a curved forceps to the bottom of the pelvis and is filled with strips of iodoform gauze, the free end of the silk thread issuing from the mouth of the pouch. When it is desired to remove the drain the gauze strips are removed and the pouch removed by making traction upon the string. I must, however, take issue with Mikulicz and his immediate followers. He speaks of an iodoform gauze drain, and any surgeon who has had considerable experience in abdominal surgery can testify to the fact that where the Mikulicz drain is called for we are frequently dealing with large cavities requiring an enormous amount of gauze. It is in such cases that I have learned to fear iodoform gauze, because the cases are by no means isolated in which a gauze drain composed exclusively of iodoform gauze became the immediate cause of death from iodoform intoxication. This is particulary liable to occur in cases in which the patient's kidneys are not functionating properly, or are diseased. It is in dealing with this class of cases that the elimination of iodoform is accomplished with great difficulty, and hence when accumulation occurs death is liable to follow from intoxication. Again, there are persons that are extremely susceptible to the local and general toxic effects of iodoform. A very small quantity of this substance may prove fatal from intoxication. I should, therefore, in using the Mikulicz drain limit the iodoform gauze to an outer layer or two and pack the pouch with ordinary sterilized gauze. This advice I am sure you will all appreciate. Drainage by using sterilized wicking has been popular in Germany for a number of years, and in many cases has answered an excellent purpose. It has never found its way to any extent into America, where gauze is employed in preference. A most excellent method of securing capillary drainage has been described by R. T. Morris (JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, July 25, 1892). To avoid the danger of hard and soft tubes and of unprotected gauze he recommends wicks, which he employs in a peculiar way. The simplest wick consists of a little roll of absorbent bichlorid gauze, around which is wrapped a couple of thicknesses of Lister's protective silk. The gauze protrudes a little from each end of the cylinder, and a few small fenestræ in the protective silk allow the serum to reach the gauze elsewhere. In certain cases where injections through a tube are desirable, the soft tube can be surrounded by this wick. When a large gauze packing for the pelvis or abdomen is needed, an apron of the silk can expand over the gauze and protect against intestinal adhesions. This method of drainage possesses great advantages over ordinary tubular and capillary drainage as heretofore described and recommends itself more especially in the surgical treatment of diffuse septic peritonitis. The prolonged contact of gauze with a serous surface is very prone to give rise to permanent adhesions as every clinician knows. In employing gauze in draining the peritoneal cavity, it is necessary to use long strips which should be inserted some distance in different directions and brought out at the same place and fastened together with a safety-pin. Van Hook has shown by his experiments that the gauze drains more freely if the external ends of the strips are left long and placed on the side of the pelvis below the level of the wound. Drainage must be dispensep with as soon as possible in order to prevent adhesions and to enable the surgeon to close the incision by secondary suturing, an important precaution against the formation of a ventral hernia. The strips should be shortened and one after the other removed as the indications for drainage disappear.

Combined tubular and capillary drainage.—The simultaneous use of a tubular and capillary drain is an excellent method of securing drainage. It is made by packing loosely a glass drain of proper length and size with strips of gauze or aseptic wicking. This manner of drainage is especially useful when the inflammatory product is serum instead of pus. It does away with the annoyance and risks of removing the transudate at frequent intervals, as is necessary in the employment of simple tubular drainage. If it is the design of the surgeon to resort to frequent irrigation after the operation, tubular drainage is necessary, but to this can be added capillary drainage by inserting strips of gauze into localities that would not be reached by the irrigating fluid.

Intra-intestinal saline injections—The value of saline cathartics in the treatment of peritonitis in its early stages not caused by perforation and after operations for peritonitis is now generally recognized. One of the difficulties encountered in the treatment of such cases is the intolerance of the stomach to food and medicines. A. J. McCosh has succeeded in securing free catharsis and in overcoming the intestinal paresis after operations for peritonitis by injecting into the intestine saline cathartics in concentrated solution. ("The Treatment of General Septic Peritonitis," *Annals of Surgery*, June, 1897.) He claims that since he has resorted to this additional procedure his results have been greatly improved. Sulphate of magnesia is injected through a hollow needle attached to a large aspirating syringe, into the small intestine, at a point in the jejunum or in the ileum as high up as possible. A saturated solution containing between one and two ounces of the salt is used. The needle puncture is closed by a Lembert suture. This suggestion certainly appears rational and should receive a fair trial by the profession.

After-treatment.—In all cases of general septic peritonitis subjected to operative treatment the most attentive and careful after-treatment is essential to success. All such patients are prostrated from the effects of the disease and the immediate effects of the operation and require a stimulating treatment. External dry heat is an important element in counteracting the direct effects of the shock caused by the operation and in restoring the peripheral circulation. The distressing thirst is quenched most effectually by the administration of water by subcutaneous infusion or rectal enemata. Strychnia and alcoholic stimulants are best calculated to increase the force of the heart's action and the tone of the arterial circulation. Partial inversion of the body by raising the foot of the bed and autotransfusion are potent means of inducing cardiac stimulation. A well-fitting abdominal bandage applied firmly exerts a favorable influence in preventing and diminishing abdominal distension. As long as nausea and vomiting persist main reliance must be placed on rectal feeding. Saline cathartics should be administered as soon as the stomach is in a condition to absorb them. Meteorism can often be relieved by high turpentine enemata and the use of the elastic rectal tube. As no operation ever secures complete asepticity of the peritoneal cavity in cases of general peritonitis, Marmorek's anti-streptococcus toxin may prove a useful adjunct to the after-treatment.

A number of cases have recently been reported in which the serum appears to have been of great value in the treatment of septic conditions in the peritoneal cavity and elsewhere. It is not probable that the serum treatment will ever displace the knife in the treatment of diffuse general septic peritonitis, but it is more than probable that it will prove to be an important therapeutic agent in the treatment of peritonitis before and after operation. Opium should be used with great caution in the after-treatment, as it is liable to cause intestinal paresis and thus increase the danger from auto-intoxication. If the peritoneal cavity has been drained with gauze the external dressing should be changed as soon as it has become saturated. The same course of treatment is to be pursued if the combined tubular and capillary drain has been used. In cases in which tubular drainage has been established the surgeon usually intends to follow the operation by continuous or periodic irrigation. If continuous irrigation is decided on the normal salt solution is the one usually employed. The solution should be used at a temperature of 105 degrees F.; the current should be small and without much force. The outflow from the peritoneal cavity should be received upon a rubber blanket and the necessary provision made to conduct it into a receptacle near the patient's bed. This method of irrigation recommends itself particularly in cases of diffuse septic peritonitis. In suppurative diffuse peritonitis periodic flushings, repeated at intervals of two or three hours, will prove of value in removing from the peritoneal cavity the fluid products of the inflammatory process. The solutions best adapted for this purpose are a saturated solution of the acetate of aluminium, a 3 to 5 per cent. solution of boracic acid or Thiersch's solution. Between the flushings the wound and openings of the drains are covered with the usual hygroscopic aseptic dressings to receive the discharge and to prevent secondary mixed infection with putrefactive bacilli. Drainage when once established should be suspended gradually and not suddenly. As soon as the peritoneal cavity and the drain canals are aseptic the external wound should be sutured to prevent as far as possible the subsequent formation of a ventral hernia.

3. PERFORATIVE PERITONITIS.—Perforation of the abdominal wall or of any of the abdominal organs containing septic material may give rise to general or circumscribed peritonitis; large visceral perforations usually result in general septic peritonitis, small perforations are preceded by visceral adhesions which limit the extension of the infection and inflammation and end in circumscribed peritonitis. Perforative peritonitis invariably occurs as a secondary affection, usually in connection with an ulcerative or gangrenous lesion of any part of the gastro-intestinal canal. Perforating ulcer of the stomach, duodenum, or typhoid or tubercular ulcers of the ileum, perforation or sloughing of the appendix vermiformis, the different forms of intestinal obstruction, are the most frequent causes of this well-defined clinical form of peritonitis. Penetrating wounds of the abdomen with visceral injury of the gastro-intestinal canal must be regarded in the same light as perforative lesions of the abdominal organs in the causation of peritonitis, and should hence be classified under this head from a bacteriologic as well as anatomico-pathologic standpoint. Perforative peritonitis is manifested by the sudden onset of the disease, by diffuse pain and tenderness, rigid abdominal walls, fever, vomiting, the impossibility by inspection, palpation and auscultation to ascertain intestinal peristalsis, the latter being almost positive proof of the presence of gas in the free peritoneal cavity. According to the author's observations, peritoneal meteorism in perforative peritonitis caused by appendicitis is rare, while he has seldom found it absent in perforations of any other portion of the gastro-intestinal canal. According to the number and virulence of the microbes which find their way into the peritoneal cavity with the extravasation, the resulting peritonitis is either diffuse or more or less circumscribed. The colon bacillus is invariably present in the inflammatory product, but in addition streptococci, staphylococci, putrefactive bacilli, the typhoid bacillus, or bacillus of tuberculosis, according to the nature of the primary affection, may also be found. Perforative peritonitis must be regarded and treated as a strictly surgical disease. The primary lesion must be exposed and treated as soon as a diagnosis can be made and the necessary measures applied to limit the extension of the infection and to prevent death from toxemia. The perforation should be found and properly treated before a general septic peritonitis has had time to develop. There are exceptions to this rule in cases where the perforation is small and the extravasation has produced a limited peritonitis in a locality where it is safe to wait for abscess formation, as is often the case in the region of the gall bladder and appendix vermiformis. Penetrating wounds of the abdomen with visceral lesions of sufficient extent to give rise to extravasation should be subjected at once to treatment by laparotomy. If at the time the operation is performed peritonitis has set in, this must receive proper attention after the visceral wounds have received the necessary treatment.

Perforating gastric ulcer.—Perforating ulcer of the stomach is found most frequently on the anterior wall of the stomach near the small curvature. According to Brinton, in 85 per cent. of all cases the anterior wall of the stomach is the seat of the perforation. Perforation in this locality is followed more constantly by diffuse peritonitis than if the posterior wall is the seat of ulceration and perforation. In seventy-five cases of perforating ulceration of the anterior wall of the stomach collected by Eichhorst, in sixty-four the perforation was complete, whereas in thirty cases at the cardiac extremity, escape of contents into the peritoneal cavity occurred but twelve times. When perforation of the ulcer into the free peritoneal cavity takes place the onset of the disease is always sudden, no matter what the antecedent symptoms may have been. Shock is present in greater or less degree. Vomiting, though frequent, is not constant. Abdominal pain and tenderness increased by pressure are nearly always present; abdominal rigidity in the early stage, and distension later on, are frequently noted. The duration of the cases vary from a few hours to five days, most of them terminating in death in less than twenty-four hours.

Treatment.—Mikulicz performed the first operation for this condition in 1883. The first successful case was reported by Kriege of Berlin. The incision should be made in the median line from the ensiform cartilage to the umbilicus, and enlarged if necessary. A long incision is required if the operation is performed after peritonitis has developed. In such cases suprapubic and epi-umbilical drainage is required after suturing of the perforation, and free flushing of the abdominal cavity is indicated. If the posterior wall is perforated and the perforation can not be reached in the usual manner, the anterior wall is incised and the perforation closed through the incision, after which the incision is sutured and the peritoneal cavity cleansed and the external wound closed if the peritoneal cavity has not become infected. Before suturing the perforation the stomach should be emptied through a stomach-tube or through the opening before suturing the perforation. It is not necessary to excise the margins of the ulcer, as these can be inverted in tying the Lembert sutures. Should the wall of the stomach in the immediate vicinity of the ulcer present an unfavorable condition for successful suturing, an omental flap or graft of requisite size should be sewed with catgut over the line of suturing.

Barling ("Perforation of Gastric Ulcer." *British Med. Jour.*, June 15, 1896) operates after the symptoms of shock have subsided. According to his experience, the prognosis is best if the operation is performed as soon as possible after the accident has occurred. In nine successful cases, collected by this author, the operation was made on an average seven and three-fourth hours after the perforation occurred, shortest interval three hours, longest ten hours. In fifteen cases which died, the average time was twenty-seven hours, the shortest interval four, the longest seventy hours. Perforation of the posterior wall of the stomach frequently gives rise to a subdiaphragmatic abscess, and when the disease resulting from the perforation has reached this stage, it must be treated in accordance with the rules that will be laid down in discussing this subject later on.

Perforating ulcer of the duodenum.—Much that has been said concerning perforating ulcer of the stomach applies to the same pathologic condition of the duodenum. The perforation occurs suddenly and frequently without any marked premonitory symptoms indicative of the existence of the primary disease. The direction in which the extravasation takes place depends on the location of the ulcer. Perforation into the free peritoneal cavity before any adhesions have taken place results in diffuse and rapidly fatal peritonitis. If perforation takes place into the lesser peritoneal cavity, circumscribed suppurative peritonitis is caused, which occasionally terminates in the formation of a subdiaphragmatic abscess.

Treatment.—It is only recently that peritonitis resulting from this cause has been subjected to operative treatment. Percy Dean, in 1894, performed the first successful operation. Grieg Smith advises incision over the seat of perforation; that is, if the condition is suspected. If we follow this rule the incision will be above the umbilicus and through the right rectus muscle. The ulcer is usually in the first part, but may be in either of the other two portions. In order to expose the lesser omental cavity we must split the gastrocolic omentum in part. The ulcer is simply inverted, excision being unnecessary. Drainage must always be provided for.

Perforating typhoid ulcer. — Perforation of a typhoid ulcer, large enough for extravasation to take place into the free peritoneal cavity, is a fatal accident, death ensuing in the course of a day or two. Perforation, however, does not always terminate in that way. Extravasation is often prevented by the affected part of the intestinal wall becoming attached to an adjoining serous surface, thus protecting the peritoneal cavity against infection. I have seen several cases of typhoid fever in which about the time that perforation is most likely to occur circumscribed peritonitis set in, which could only have been caused by a perforating ulcer under such favorable conditions, and from which the patients recovered without operative intervention.

Treatment and results.—Kussmaul was the first to perform laparotomy, excise and suture a perforating typhoid ulcer. The operation was performed October 1885. Luecke (*Deutsche Zeitschrift f. Chirurgie*, 1888) reports a case in which he performed laparotomy for the same indication Oct. 22, 1885. A large perforation was found, excised, and the edges sutured. The abdominal cavity was washed out with salicylated water, the wound sutured except a space left for a large tubular drain. The patient died in seven hours. A pint of fluid with a fecal odor was found in the pelvic cavity. Luecke in connection with the report of this case suggested the performance of the operation in two stages, the perforated intestine to be fastened to the abdominal wall in the wound in the first, and the direct treatment of the perforation later. The following three years the operation was performed by Bontecou, Bartlett and T. G. Morton with no recoveries. Van Hook (*Medical News*, Vol. 50, No. 217) reports three cases treated by laparotomy and suturing of the perforation, of which one recovered. He collected nineteen cases of which four recovered. He places the line of sutures parallel to the long axis of the bowel and flushes the peritoneal cavity with a thick stream of sterilized salt solution at a temperature 105 to 112 degrees F.

Wiggin (*Medical Press*, Jan. 1, 1896) collected twenty-four cases of perforating typhoid ulcer subjected to laparotomy with six recoveries. If those cases are rejected in which the diagnosis is somewhat doubtful, there are seventeen patients with three recoveries. The first successful result was obtained by Van Hook, the second by Netschajans, the third by Abbe. J. Price has recently reported three consecutive operations with as many recoveries, a surgical feat which it will be difficult to duplicate. The writer has performed the operation three times with one recovery. The feasibility and justifiability of abdominal section for perforating the typhoid fluid ulcer have been established in view of the fact that all of the patients who have been operated on would have died without the operation. The operation should be performed as soon as possible after the accident has occurred. The mortality will always remain great owing to the debilitated condition of the patients and the existence of multiple ulcers. The incision is made through the median line between umbilicus and pubes and at least large enough to insert a hand. The first point to be sought for is the ileocecal region, when search is made for the perforation in an upward direction replacing the part of the bowel examined so as to prevent extensive eventration. Excision of the ulcer is unnecessary as its margins can be inverted by the Lembert stitches which should be placed transversely and not in the long axis of the bowel as advised by Van Hook. Should the serous surface over any other ulcer present indications of an approaching perforation it should be covered with an omental flap or graft fastened in place with a few points [illegible]

Flushing of the abdominal cavity with a warm physiologic solution of salt followed with Thiersch's solution and free drainage are strongly indicated and should invariably be carried out. If the patient is much prostrated, Luecke's suggestion to perform the operation in two stages should receive serious consideration. If the perforation has resulted in circumscribed suppurative peritonitis, incision and drainage of the abscess cavity are indicated, leaving the perforation to heal spontaneously or to be closed by a subsequent operation.

4. CIRCUMSCRIBED PERITONITIS.—A circumscribed peritonitis is an inflammation of the peritoneum during which a greater or lesser part of the peritoneal cavity becomes excluded from the original source of infection by the formation of plastic visceral, parietal, or visceral and parietal adhesions. The complexus of symptoms varies according to the degree of virulence of the microbic cause, which only occasionally is overshadowed by the primary affection. The symptoms appear suddenly, or are preceded by those incident to the primary disease. The severity of the pain and the extent of muscular rigidity and tenderness will correspond with the extent of the disease. The intensity of the general symptoms are determined more by the nature and virulence of the microbic cause than the area of the peritoneal surface involved. The inflammatory focus may be limited to a very small space, or it may involve the greater portion of the peritoneal cavity and organs which it contains. The clinical course and termination are determined largely by the nature of the bacterial cause, the anatomic location of the primary starting point and nature of the environment. Localized peritonitis is most likely to occur outside of the limits of the small intestine area. If the organs adjacent to the primary focus of infection are favorably located to limitation of the process, diffusion is frequently prevented by the formation of adhesions. This is especially true in cases where the primary infection is limited by the existence of old adhesions. Localized peritonitis may be confined to the lesser omental cavity, particularly in cases of perforating ulcer of the stomach and duodenum. More frequently it is caused by appendicitis and cecitis. A very frequent cause of circumscribed peritonitis is inflammation about the gall blader, uterus, Falliopian tubes and ovaries. The localized form of peritonitis is very often overlooked during life. It can usually only be detected if a demonstrable swelling forms at the seat of inflammation. The mildest form of infection gives rise to fibrinoplastic peritonitis which leaves temporary or permanent adhesions, but terminates without suppuration. Circumscribed suppurative inflammation is always attended by fibrinoplastic peritonitis the products of which and the viscera which it involves form the abscess wall. The microbes which most frequently produce fibrinoplastic peritonitis without suppuration are the gonococcus and staphylococci. Circumscribed suppurative peritonitis is usually the result of infection with staphylococci, bacillus coli communis and pneumococci. In fibrinoplastic peritonitis surgical interference only becomes necessary when intestinal obstruction is caused by adhesions. In circumscribed suppurative peritonitis the pus should be evacuated as soon as the disease is recognized and if possible by an extraperitoneal route.

Acute tubercular peritonitis.—Tubercular peritonitis met with in the majority of cases in the circumscribed form occasionally presents itself as a widely diffused acute affection. The rapid diffusion in the peritoneal cavity, either through the circulation or by rupture of a tubercular abscess into the peritoneal cavity, or by extension from a tubercular salpingitis, occasionally gives rise to a form of acute peritonitis characterized as such in a modified way by the clinical manifestations which accompany it. According to the intensity of the infection or the degree of susceptibility of the patient to the action of the tubercle bacillus, the disease assumes one of the following pathologic forms: 1. Tubercular ascites. 2. Fibrinoplastic peritonitis. 3. Adhesive peritonitis. Suppuration only takes place when the tubercular product becomes the seat of a secondary mixed infection with pus microbes. Laparotomy is now a well established operation in tubercular peritonitis. The exact manner in which the operation exerts its therapeutic influence is not well understood.

Nannotti and Baciocchi (Hildebrand, *Jahresbericht f. Chirurgie*, 1896, p. 661) studied the curative effect of incision and drainage for peritoneal tuberculosis experimentally produced on rabbits and dogs. The operation yielded only temporary improvement in rabbits, but usually resulted in a permanent cure in dogs. They found, soon after the operation, a decided local reaction in the periphery of the tubercle nodules, an increased phagocytosis which in dogs brought about absorption of the tubercular product and formation of new connective tissue. Irrigation of the peritoneal cavity did not appear to add to the therapeutic effect of the operation. According to these investigators, the curative influence of the operation is to be attributed to the local reaction which it induces, and by increasing the absorptive power of the peritoneum. The writer has obtained very satisfactory results in cases which resisted laparotomy and drainage by repeated tappings and injections of two to four drachms of a 10 per cent. iodoform glycerin emulsion.

Suppurative peritonitis.—Suppurative peritonitis, *i. e.*, an inflammation of the peritoneum which results in the formation of pus, is always more or less circumscribed. This form of peritonitis is most frequent and is generally associated with fibrinoplastic exudation. The pus is either serous, seropurulent, or may reach the consistence of cream, when it is usually of a yellow color. The accumulation of pus may be so large that upon opening the abdomen it may appear as though the entire peritoneal cavity and all of the organs contained within were implicated, but a careful examination will almost always reveal the fact that a large part of the peritoneal cavity and many of the organs were shut out from the inflammatory process by plastic adhesions. Suppurative peritonitis must therefore be regarded from a practical standpoint as a circumscribed inflammation. The appearance and character of the pus are often greatly modified by the admixture of an extravasation accompanying the perforative lesion which produced the peritonitis. If the pus is thin, serous, we speak of a seropurulent peritonitis. It is a serous peritonitis with the formation of pus in sufficient quantity to render the serum more or less turbid. This subvariety of suppurative peritonitis is without exception in combination with fibrinous exudations which tend to limit the extension of the infective process. Sedimentation of the solid constituents takes place, so that the fluid contains more of the solid matter in the most dependent portion of the affected district.

III. *Plastic peritonitis.*—A very frequent form of circumscribed peritonitis is the one in which the inflammatory exudate is composed largely of fibrin—fibrinoplastic peritonitis. It is usually a secondary process following a primary affection of one of the abdominal or pelvic organs, and denotes a mild form of infection the extension of which becomes limited by firm adhesions. The inflammation results in plastic exudation with little or no effusion. The character of the exudate depends on the intensity and quality of the bacterial cause. The exudation is often so copious that it has been mistaken for malignant disease. The distinguishing features of this form of peritonitis from abdominal tumor are less circumscribed outline, the lesser resistance offered, the more regular surface and the fact that ascitic fluid is not bloody, but serous or seropurulent. The exudation in the course of time contracts and results in strong bands of adhesion which frequently fix and distort the organs to which they are attached, which has given rise to another term, *peritonitis deformans*.

Treatment.—The surgical treatment of circumscribed peritonitis by abdominal section has yielded very encouraging results. In many of these cases the surgeon is able to reach the abscess and gain access to the primary lesion without invading the peritoneal cavity. In such instances the operation is an *celiotomy* and should be distinguished from the operation in which the free peritoneal cavity must be invaded to reach the pus cavity, which is then an *abdominal section* in the sense in which this expression is used in surgical language. The extraperitoneal route is the operation of choice in all cases in which the abscess cavity can be safely reached and efficiently drained by this method. In circumscribed accumulations of pus in the peritoneal cavity, in which the seat of the disease must be reached through the free abdominal cavity, the safest course to pursue is to perform the operation in two stages. The first operation then consists in suturing the parietal peritoneum to the wall of the abscess cavity, suturing the abdominal incision with the exception of a space large enough to incise and drain the abscess cavity later. This space is packed with iodoform gauze, and two or three days later the abscess is incised and drained. If the symptoms are urgent and the operation must be completed, the contents of the abscess cavity should be removed by aspiration, after which the suturing can be more thoroughly done, when the abscess can be incised and drained with less risk of infecting the peritoneal cavity than without preliminary evacuation by the use of the aspirator. These methods of treatment are especially applicable for single pus cavities. If the disease is more diffuse, involving a number of abdominal organs, and the abdominal incision reaches at once the infected territory, pus wherever found must be removed by flushing or by mopping with a soft sponge. In fibrinoplastic peritonitis without suppuration no attempt should be made to tear the adhesions except they have caused intestinal obstruction, when the raw surfaces are dusted with aristol, which, as has been shown by the experiments and clinical observations of R. T. Morris, is the most efficient way to prevent recurrence of the adhesions.

[illegible] ("Ueber die Erfolge der chirurgischen Behandlung der diffusen eitrigen Peritonitis und peritonealen Sepsis," [illegible] No. [illegible], 1888) admits that in cases of peritoneal sepsis, the most acute and gravest form of infection, surgical treatment is of no avail. In general and circumscribed suppurative peritonitis operative treatment is indicated. Evacuation and removal of the pus with sponges are not permissible, as animals thus treated invariably died. Experiments on animals as well as clinical observation satisfied [illegible] that multiple incisions, drainage and irrigation with salt solution proved successful in thoroughly cleansing the peritoneal cavity without causing shock.

Winkler ([illegible] No. 28, 1888) advises that in progressive fibropurulent peritonitis the adhesions should not be disturbed, and each abscess should be evacuated separately in order to prevent fresh infection from the liberated contents of these encapsulated foci of infection. In one case six intraperitoneal abscesses were evacuated through as many incisions at four consecutive operations. The diagnostic indications of such abscesses are increased resistance, tenderness, dulness and elevated temperature. In cases of doubt an exploratory puncture should be made. The abscess cavities should be drained with iodoform gauze. Some surgeons pursue a more aggressive course and are not content in removing the fluid pathologic product, but aim to remove at the same time the fibrinous exudate. At the meeting of the French Surgical Congress ("Transactions," 1896) Demons made a strong plea in favor of early operative intervention and the removal of fibrinous deposits. In 1886 he had under his care a woman suffering from suppurative peritonitis following suppuration of an ovarian cyst. Her condition at the time of operation was critical. He opened the abdomen, evacuated the pus, removed the cyst, and with a rough sponge and blade of a knife scraped the entire surface of the intestines; a most satisfactory recovery followed. He deemed it advisable to scrape the inflamed surfaces as more efficacious and affording less risk of missing portions of the exudates. In a similar case he assisted Denuce in performing this radical method of cleansing, and the patient rapidly recovered. There are few surgeons who would today follow his example. Adhesions tend to limit the infective process and should be interfered with as little as possible in the search and liberation of pus.

Körte ("Erfahrungen über die chirurgische Behandlung der allgemeinen eitrigen Bauchfellentzündung," Archiv f. klin. Chirurgie, Bd. [illegible]) saved six out of nineteen cases of acute general suppurative peritonitis treated by abdominal section. All cases without adhesions and peritoneal sepsis died, also all cases operated upon after the fourth day. He cautions not to separate adhesions and is content in evacuating the pus and establishing drainage. The closure of perforations should be left unless it can be done without additional risk.

3. HEMATOGENOUS PERITONITIS.—The existence of primary peritonitis without an antecedent injury, lesion and direct source of infection is looked upon with suspicion by most modern pathologists and surgeons. Idiopathic peritonitis so-called [illegible] tonitis does occur, but is much more [illegible] affections of the pleura and pericardium [illegible] mary affection peritonitis is [illegible] during [illegible] able that the [illegible] which [illegible] toneal cavity through [illegible] nitis is always caused by [illegible] peritonitis that [illegible]

source of infection is the result of an infection through the blood, and should be called hematogenous or metastatic peritonitis. It has been observed in connection with nephritis, pyemia, rheumatic arthritis and acute exanthematous diseases. In the absence of even a distant focus of infection it is plausible to assume that peritonitis in very rare cases is caused by the localization of pus microbes derived from the circulating blood in some part of the peritoneum prepared for their reception and growth by some antecedent disease or injury. In primary peritonitis the disease is not preceded by any symptoms which would suggest the existence of an antecedent disease or injury. Hematogenous peritonitis assumes different pathologic types, resembling in this respect peritonitis produced by direct local causes.

Treatment.—The surgical treatment must be guided by the location and extent of the disease, the existence or absence of complications, and the pathologic type the disease presents at the time of operation. The absence of primary visceral disease of any of the abdominal organs is a favorable item in the prognosis and in the technique of the operation to be performed in the surgical treatment of this form of peritonitis.

6. Visceral Peritonitis.—A localized peritonitis that can be brought in direct etiologic connection with the organ primarily affected is expressed by a compound word, with the prefix *peri* and the noun used to indicate the organ primarily affected in a state of inflammation. The inflammatory process is seldom limited to a single organ, as during the course of the disease adjacent organs or the parietal peritoneum will surely become involved. The nomenclature of visceral peritonitis is a lengthy one, as it includes all of the abdominal and pelvic organs from which, when the seat of a suppurative inflammation, may come the primary starting point of an attack of localized or diffuse peritonitis. The mesentery and omentum are modified forms of the peritoneum, and when the seat of inflammation we speak of a mesenteritis and epiploitis. In inflammatory and traumatic affections of the abdominal walls and the abdominal and pelvic viscera, plastic inflammation of the omentum frequently constitutes the safeguard against infection of the general peritoneal cavity by the omentum becoming firmly attached over a threatened perforation or visceral or parietal wound, thus affording protection against infection from within and without. On the other hand such adhesions between the different abdominal viscera, and the viscera and any portion of the abdominal wall are often transformed into firm bands of adhesions which later on so frequently become a direct cause of intestinal obstruction. The surgeon often imitates nature's process and makes use of the omentum in covering denuded surfaces or in suturing tissues of doubtful resistance, and in covering surfaces of the gastro-intestinal canal the seat of a threatened perforation. In visceral peritonitis the primary disease often furnishes the special indication for which the operation is performed. Inflammation of the gall bladder often gives rise to inflammation of the serous investment of a number of adjacent organs resulting in succession in pericystitis, epiploitis, perigastritis, perihepatitis and peri-enteritis. The removal of the original cause which provoked the primary disease furnishes the main indication in the treatment of such extensive pathologic indications. The surgical treatment of appendicitis and its various complications is not well settled at the present time. Some surgeons advise operation in all cases in which a diagnosis of appendicitis can be made, regardless of the nature of the disease and the character of its complications. The more conservative element of the profession limit the use of the knife to cases in which there are positive indications for surgical interference. For my own part I resort to operation in all cases, during a first attack, when the symptoms point to perforation or gangrene of the appendix. The sooner the operation is undertaken under such circumstances the better the results. The appendix should only be sought for and removed if pus is found in the iliac fossa, when this can be done without a material increase in the immediate risks of the operation, otherwise the treatment by incision and drainage will yield the best results. In mild cases of appendicitis, from 80 to 90 per cent. recover under appropriate medical treatment, and in a fair percentage of cases the disease does not return. The gravest cases are those in which the affection of the appendix is followed by diffuse peritonitis. In the treatment of this class of cases nearly all surgeons are fully in accord with the rules laid down by McBurney (*Medical Record*, No. 13, 1895). This surgeon reports twenty-four cases of diffuse peritonitis caused by appendicitis treated by abdominal section, of which number fourteen recovered. He prefers glass tubes to rubber drains. The glass tube is loosely packed with sterile gauze and inserted to the floor of the pelvis. He irrigates with a hot sterile salt solution. The incision, four to six inches in length, is made from a point near the anterior superior spine of the ilium following the direction of Poupart's ligament and about an inch above it. Adhesions are interfered with as little as possible. Collections of pus or seropurulent fluid are searched for and evacuated. After removal of pus with sponges, irrigation is practiced. If fluid is found outside of the pelvis, strips of iodoform gauze are used to drain the different spaces. At the end of twenty-four to thirty-six hours the glass drain is removed and a strip of gauze inserted in its place. If the clinical history reveals the fact that during the first or any subsequent attack an abscess in the vicinity of the appendix has ruptured into the cecum, I should hesitate to recommend an operation, as such cases usually recover spontaneously in the course of time, an operation for such a condition is attended by many and serious risks. The writer has operated in four cases, in which the balance of what remained of the appendix was removed, the opening in the cecum sutured, two of which recovered and two died of septic peritonitis within three days after the operation. In relapsing appendicitis an operation is indicated, particularly in cases in which the attacks set in at short intervals and with gradually increasing intensity.

In peritonitis resulting from infective lesions of the female internal genital organs, the uterus, ovaries and Fallopian tubes, the organ primarily affected and the resulting intraperitoneal abscess can often be reached more safely by a vaginal than by an abdominal operation. Occasionally the combined operation will afford greater safety, more complete removal of the infected tissues and organs, and more efficient drainage.

7. Pelvic Peritonitis.—Pelvic peritonitis is seldom met with in the male. It is a form of peritonitis in which the female pelvic organs are the primary starting point of infection with extension to the periton-

eum, either through the Fallopian tubes, or the lymphatics of the uterus or its adnexa. It is caused most frequently by gonorrheal or puerperal infection, or develops after instrumental examination of the interior of the uterus or operations upon this organ. In pyogenic infection the inflammation may become diffuse, and if circumscribed usually leads to the formation of parametritic or intraperitoneal abscesses, or pus formation takes place in both of these localities. In the peritoneal cavity the gonococcus produces a plastic peritonitis, and sometimes localized suppuration. Salpingoperitonitis and more diffuse pelvic peritonitis are most frequently caused by gonococcus infection. Ceppi (*Revue Méd. de la Suisse Romande,* 1888) reported the first case of laparotomy for gonorrheal peritonitis. Gonococci were found in the pus cells. The patient recovered. Abdominal section is seldom performed for gonorrheal peritonitis during the acute stage. Opening of the abdominal cavity by this route is usually reserved for the removal of the remote consequences of the disease, and the operation usually includes the removal of the adnexa on one or both sides. An early incision through the vaginal roof into the *cul-de-sac* of Douglas in the treatment of pelvic peritonitis, so strongly urged and frequently practiced by Henrotin, is a rational procedure and frequently succeeds in preventing the extension of the infection, and the occurrence of serious remote complications. I have in several instances incised and drained the Fallopian tube through such an incision, and in this way prevented further leakage from the tube into the peritoneal cavity, and thus directly cut off additional supply of infectious material. The treatment of large parametritic abscesses extending to the brim of the pelvis and above it by making an extraperitoneal incision the same as is resorted to in ligating the external iliac artery, a procedure advocated by Pozzi, is preferable to a transperitoneal operation in all cases in which the abscess can be reached by this route.

Birnbaum (*Der Frauenarzt,* July 7, 1894) advises in puerperal sepsis in which a pelvic exudate has been thrown out, if continued high fever persists, drainage of the abcess as required. When fluctuation is detected an incision is made from 1 to 2 centimeters above Poupart's ligament and from 2 to 3 centimeters from the anterior superior iliac spine. When fluctuation is not positive exploratory puncture is recommended; vaginal exploration and incision are indicated when the abscess is located lower down in the pelvis. We shall hear less of intestinal, vesical and rectal fistula in the future, as the remote results of pelvic peritonitis or parametritic abscesses, as soon as the profession recognizes fully the importance and necessity of timely operative interference.

8. PUERPERAL PERITONITIS.—By the term puerperal peritonitis is understood a progressive inflammation of the peritoneum occurring in consequence of an extension of an infection from any part of the genital tract in puerperal women after delivery or abortion. The infection usually takes place through the lymphatics, which in the majority of cases terminates in diffuse septic peritonitis. In some instances the disease remains limited to the pelvic organs and their serous investment, when abscess formation intra- and extra-peritoneal is very likely to occur. The infection in such comparatively mild forms of puerperal sepsis is usually caused by the different varieties of the staphylococcus while the diffuse septic puerperal peritonitis is nearly always produced by the streptococcus.

Treatment.— The treatment of the localized form of puerperal peritonitis is the same as that we have advised in circumscribed peritonitis resulting from other causes. The foudroyant form of puerperal sepsis proves fatal in spite of the most energetic medical and surgical treatment. The use of the antistreptococcus serum may prove of great value and should receive an early and fair trial. It has been suggested that early removal of the infected uterus would prevent the extension of the disease to the peritoneum and death from sepsis. A number of vaginal hysterectomies have been performed for this indication, but on the whole the results have not been encouraging. It is exceedingly difficult, and in many cases absolutely impossible, to make a sufficiently early and positive diagnosis to warrant such a grave and mutilating operation as a timely and life-saving measure. If the uterus is removed after general septic peritonitis has developed, the operation is performed too late, and death from shock and sepsis is the rule. Professor von Winckel ("Ueber die Kölotomie bei der diffusen, eitrigen puerperalen Peritonitis," *Therapeut. Monatschefte,* Heft 4, 1895), is not in favor of resorting at once to the removal of the uterus and adnexa by the vaginal route. In cases in which the Douglas *cul-de-sac* is prominent in the vagina, he recommends a broad and free incision behind the uterus. If the inflammatory product is not within safe reach of a vaginal incision he advises abdominal section. He is in favor of vaginal hysterectomy only in cases in which a double parametritis sets in after such a procedure.

9. SUBDIAPHRAGMATIC PERITONITIS.—A peritonitis limited to the under surface of the diaphragm and any of the adjacent abdominal organs is called subdiaphragmatic peritonitis. If the inflammation remains limited and life is sufficiently prolonged, it usually terminates in the formation of a subdiaphragmatic or subphrenic abscess. Perforating ulcer of the stomach and duodenum, abscess of the spleen and liver, are the most frequent affections which precede subdiaphragmatic peritonitis. Maydl has wrtiten the most complete treatise on subphrenic abscesses, dividing them into twelve groups according to their location and the organ from which they have their starting point. The diagnosis is usually difficult and Maydl recommends the exploring needle very strongly as an important diagnostic resource. The abscess often ruptures into the pleural cavity. The abscess is most frequently reached through the pleural cavity, which is sometimes found obliterated where the puncture and incision are made through the diaphragm. In cases of empyema of the pleural cavity the possible existance of a subphrenic abscess must be kept in mind.

Witthauer ("Über Magenperforation and subphrenische Abscesse," *Therapeut. Monatshefte,* October, 1895), reports two cases of subphrenic abscess caused by perforation of the stomach, which terminated fatally without operation. In the first case carcinoma of the stomach was diagnosticated, in the second the diagnosis was first made of perforating ulcer of the stomach but was later doubted, as the usual symptoms of peritonitis did not appear. A similar case is reported by Schesinger. Trojanow (*Annalen der russ. Chirurgen,* 1896, Heft 3) reports a case of subphrenic abscess which had its starting point in a splenic infarct which occurred during an attack of typhoid fever. He resected the tenth rib between the axillary line and scapula, found the pleural cavity at that point obliterated, and at once incised the diaphragm, opened and drained the abscess, in the contents of which fragments of necrosed splenic tissue were found. In cases in which the pleural cavity is not found obliterated, he advises suturing of the pleura to the diaphragm before opening the abscess. A valuable contribution to the statistics and surgery of subphrenic abscesses has recently been made by C. Beck of New York (*Medical Record*, Feb. 15, 1896). He reports five cases treated successfully by operative interference. Rib resection and opening of the pleural cavity usually become necessary as preliminary steps in opening a subphrenic abscess. Accurate location of the abscess and a positive diagnosis are made by exploratory puncture. As perforating ulcer of the stomach is the most frequent cause, subphrenic abscesses are more frequently located on the left than the right side. Occasionally a spontaneous cure occurs by perforation of the abscess into a hollow adjacent organ. Maydl has shown that out of 104 cases not operated on only six recovered, while out of eighteen cases operated on only 11 per cent. died. The satisfactory results of the operation furnish the most conclusive proof regarding its necessity and life-saving value.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
BY CARL H. VON KLEIN, A.M., M.D.

(Continued from page 484.)

XII.—FRENCH AND ENGLISH WAR SURGERY.

The beginning of the French war surgery; The first flying and stationary hospitals; Improvements under Louis XIV. and XV.; Organization of war hospitals and military physicians under Louis XVI. and the Republic; Means of transportation; Ravaton, Colombier; Trecourt, Lombard, Percy, Moreau, Boy; English regulations; the lash; J. Hunter, Jackson; J. Pringle, fresh air, recreation of the sick; Brocklesby, barracks; Count Stair, treaty for the protection of the wounded; French and German voices concerning barracks and protection treaty.

From the downfall of the Roman Empire to the time of the crusades one hears nothing of military surgery; it was dormant and awakened first in *France*. When Louis the Good made a pilgrimage to the Holy Land, Pitard was the first surgeon who accompanied the army with a few others, almost all monks or priests who along with their clerical functions also gave medical treatment. The later generations troubled themselves but little over the care of the wounded warriors. For their personal attendance alone, the kings, barons and generals took surgeons with them to the war, and these also occasionally treated the officers for a compensation, but they were never obliged to do so. The common soldier was left to the quacks who preyed on the army with their wound balsam and secret remedies. Women established themselves on the battlefields; they adjusted bandages and washed out wounds. Such was the condition in France and everywhere. Although through the introduction of shotguns, a great change took place as well as in the manner of fighting, which was no longer between individuals but between large masses, as in the kind of injuries sustained, and the number of wounded was enormously increased; still military physicians were never appointed. Ambroise Paré, who during the war from 1536 to 1569, although in the service of only a single prince, first extended his help in a large measure to the wounded soldiers, can therefore be regarded as the first qualified military surgeon. How great respect this surgeon enjoyed in the French army was shown in the hard-pressed fortunes of Metz, whose completely discouraged garrison felt that his arrival was the greatest reinforcement which they could receive. His king, Charles IX., saved him to the Reformists on the night of St. Bartholomew.

The great confidence which the troops felt in him and in his pupil Pigray, who, placed under similar circumstances, had never refused his assistance to the soldiers, was the inducement which moved Henry IV. to organize the military medical system. In 1591 the king issued a decree for the care of the wounded, and in 1597, at the siege Amiens by Sully, he established the *first portable hospital* with a surgeon-major at the head. This new creation was christened by the French with the new name "ambulance," a word which had not before appeared in their language. Under Louis XIII., besides the portable hospitals (Hôp. ambulant), which followed the army, there arose also *fixed military hospitals* (Hôp. sédentaire, the first one at Pignerol), of which Cardinal Richelieu regarded himself as the founder. To each regiment a surgeon-major was now appointed. The wars of *Louis XIV.* made new improvements necessary. The king increased the number of stationary and portable hospitals as well as the number of physicians. He appointed to the ambulances and to each regiment, subordinate to their chief, an over-surgeon (chirurgien-major), under-surgeons (sous-aide-major), assistant surgeons (aide-major chirurgien) and students. With all of these a surgeon-major was provided for consultation.

Under Louis XV. institutions for the training of military physicians were first established, and by him and his successor repeated decrees were issued for the better organization of the sanitary system. France led all other countries and served as an example to them. They opened the amphitheaters in Lille, Metz and Strassburg, and erected two new ones in Brest and Toulon, where for the education of skilful physicians medicine and surgery, together with the supplementary sciences, were taught. In order to learn the nature of a field-hospital under Louis XV., we may consider the plans of Ravaton, at that time military surgeon. A field-hospital for 20,000 men should have an able surgeon-major at its head who should in every case be chosen from the military hospitals; also twelve chirurgiens aides-major, and thirty students who should be chosen only according to merit and not by favor, and thirty attendants. There should be in addition a war commissary, director, sub-director, cook, butcher, baker and three priests, so that the whole field-hospital includes 134 persons and forty-six horses. They carried crucifixes and all the accessories with which to celebrate mass; there were also six complete surgical instrument chests, six tackles, 1,000 pieces of bandage cloth, ten centners of lint, 10,000 strong needles, etc. In the enormous store of medicines there were, among other things, 200 pounds of licorice, 150 pounds of senna, 200 pounds of turpentine, 200 pounds of manna, 400 pounds of eau de vie de France, 100 pounds of olive oil and 150 pounds of ungt. basilicum. Ravaton assumed that in the beginning of a campaign 3 per cent of the troops would be sick; in the middle of the campaign 5 or 6 per cent.; and at the end from 10 to 12 per cent.; while after a battle which had raged from morning till evening, he assumed that 10 per cent. of the troops would be wounded.

Under Louis XVI. each army had a consulting surgeon, whose advice was sought when new field-hospitals were laid out, in important surgical cases and in all scientific questions. On the other hand the surgeon-major of the army, the distribution of the wounded, and in short, the mechanical part of the service. (This arrangement corresponds nearly to the present consulting surgeons and general physicians of the Prussian army.) In the portable hospitals, only the first and most necessary aid was extended, and none were admitted who could be safely transported to a stationary hospital. The military physician, Colombier, at that time required that the hospital be isolated, located near a river but high and dry, have lofty rooms, chimneys and lofty windows provided with green curtains. The water closets were to connect with running water and be provided with gypsum instead of wooden bowls. The beds were to be of straw and all coverings of linen, never of wool, while the physicians, surgeons and apothecaries were to reside within the hospital. Besides these regular field-hospitals, Colombier proposed a hospital for each regiment, consisting of its own wagons and tents under which the patients could be sheltered as soon as the regiment made a halt. In this way the sick soldier stayed with his own regiment and was not sent into a field-hospital for any slight cause. The regimental surgeon knew his own people well and could treat them better. In this way they also avoided the practice of sending the patients from one surgeon to another, and from one hospital to another, remaining so short a time in each that their disease could neither be properly diagnosed nor treated. Colombier did not intend with this plan to entirely do away with the great field-hospitals, but to diminish their number. He interested himself in the whole subject of a sanitary system and recommended among other things that the soldier wear a leather waistcoat and breeches, polished half-boots, a buckram coat and a hood of oil-cloth in order to protect the head from rain. cold and sun. On account of vermin the hair was to be cut short; the marshal of Saxony had the heads of his people shaved close. He recommended meat frequently but in small quantities as it spoiled easily, and furthermore recommended the cultivation of potatoes in France according to the German custom in order to provide them for the troops. The head of the hospital was the chief-surgeon. He performed all the serious operations himself, but a physician was required to be present, and was generally called for consultation in all important cases. Only the more skilful under-surgeons and assistant surgeons were allowed to operate, and then only with the consent of the war commissary, and under supervision. When the physicians made their visits these assistants put on the bandages and could at the same time consult in any special case; but the bandage was not prepared until everything else had been properly made ready in order that the wound might not be too long exposed to the open air. Afterward they fumigated with juniper and the like. Upon penalty of a fine of 1,500 livres no hospital director dared use brandy, either in bandaging wounds or in the preparation of medicines. and every surgeon or apothecary who used it ran the risk of being dismissed from the service. Physicians as well as surgeons were responsible for the quality of the medicines and food. The students, for the most part taken from the amphitheaters, slept in the hospital and had charge of the diet of the patients and of the force of nurses; they allowed one student to ten officers or twenty-five patients. and one nurse to two officers or fifteen patients. If one of them fell asleep during his watch he was fined 20 sous; whoever left the ward was dismissed. Each one of the wounded had his own bed, if it was at all possible, to which a tablet was attached upon which name, number of bed, disease, day of entrance, food and medicines were written. Woe to the soldier who was the third time treated for syphilis! as a punishment he had to serve two years longer. In order to turn this material to the account of science special regulations were enacted. Aside from the fact that in particular cases sections were made, the chiefs of the hospitals submitted reports to the state secretary of the war department to the inspector of physicians (Médecin-inspecteur titulaire), and of surgeons (chirurgien-inspecteur titulaire). They both conducted a correspondence with all the hospitals and passed their opinions on the reports of cases. The most valuable of these were collected by a specially appointed old military physician under the title of *Médecin consultant de l'armée*, and after the Royal Society of Physicians had passed upon them were published. The journal for this purpose appeared quarterly at the expense of the State. This custom was originated by Louis XV., who ordered all the surgeons of the field-hospitals to submit their most important notes as well as a report on the topography and the epidemics of the hospitals. Richard de Hautesierk, at that time chief military physician, published these collections as "Recueil d'obs. de Méd. des Hôpit. milit." (2 Vols. 1766, 72.) The yearly salaries of the French military physicians in 1781 were as follows:

Médecin-inspecteur titulaire	10,000	livres.
Chirurgien-inspecteur titulaire	6,000	"
Médecin consultant des camps et armées, 1,000 to	5,000	"
Physicians and chief surgeons according to the rank of the hospital, 500, 800, 1,000, 1,500 and	2,000	"
Under-surgeons, with board	288	"
Assistant surgeons, with board	252	"
Students, with board	96	"
Nurses, with board	120	"

Under Louis XVI., the sick soldiers were cared for at a comparatively greater expense than in other countries. Nowhere in Europe, were there at that time, military hospitals to compare with those in the French garrison cities, where they were divided into five classes according to their size, and provided with a sufficient number of physicians and surgeons. Under the supervision of the latter, the field-physicians gave their services when necessary; accordingly there was no army in which the military physicians were so much respected as the French; for the Prussian soldier did not consider his steward as belonging to the military class and regarded any subordinate officer as a person of more consequence than the regimental physician

The *republic* made every citizen a soldier. It could be relied upon, that the sick officer could lay no claim to better treatment than the soldier, and they took even better care than before, that the wounded should receive proper nursing. The highest authority lay with the physicians, surgeons and apothecaries, comprising the conseil de santé in Paris, which was subordinate to the minister of war, and met daily, making up the personel of the physicians in the army. according to examinations previously held, and receiving fortnightly reports from the hospitals and the different bodies of troops. Each army had its chief physician and chief surgeon. As the chirurgien-consultant and the chirurgien-major de l'armée found their duties frequently conflicting, both offices were abolished and replaced by a chirurgien en chef de l'armée. There was only one class of physicians, while the surgeons and apothecaries were divided into three classes, according to their knowledge, merit and seniority. The physicians wore grayish blue coats with black velvet collars, with gold cord and black facings; the surgeons and apothecaries wore light blue coats with red cloth waistcoats and breeches. The different borders distinguished the three classes. The yearly salaries of the hospital physicians, who were paid *monthly*, was under the republic, as follows:

Chief physicians, chief surgeons and chief apothecaries	7,200	livres.
Physicians, surgeons, apothecaries, first class	4,800	"
Surgeons, apothecaries, second class	3,600	"
Surgeons, apothecaries, third class	2,400	"
Nurses, first class	1,080	"
Nurses, second class	720	"

When a battle took place, the chirurgien en chef summoned all the surgeons who could be spared from the stationary hospitals and the troops, to the *field hospitals* in every head-quarters; the over-physician and the over-surgeon collected their subordinates, a corps of whom were alloted to each army, and apportioned them among the hospitals. On the day of battle, a depot containing sufficient bandage-material, wine, bouillon, etc., was erected one or two hours march behind the army. From this point, three detachments, which were in touch with the center and both wings of the army, and could unite if necessary, were formed. Each detachment had a sufficient number of litters and wagons for transportation. The train wagons, which carried the apparatus of the field hospital, were drawn by four horses, were covered with oil cloth, and bore the words in large letters, "Hôpital ambulant nr. . . ." The wounded were first received into the field hospital where an immediate examination was made. In order to have enough room in this hospital, as many as possible were transferred daily to the nearest hospital, and no one was admitted who could endure the journey to a stationary hospital. Soon after the battle, the regiments sent a few officers to the hospitals to find their sick and furnish them with billets d'entrée, as no one could be accepted without these. Wine, meat and bread (auf Bons), and mattresses were required to be furnished by the community. In spite of the comparatively good equipment of the field hospitals under the republic, the mortality, especially in cases of amputation, was enormously large.

At that time, in France, they performed operations which should not have been allowed, in order to boast of them; it is known that a military surgeon in the beginning of the year 1796 had made over 400 amputations. A great and frequently a very injurious abuse, as Wardenburg noted, was practiced with the roller bandage, and he said that especially in the field hospitals, where there was so much to do, the use of the sling bandage and of cloths would be much simpler (l. c. I, p. 71. The same idea was later advanced by Esmarch). There were *stationary hospitals*, as already mentioned, in all the garrison cities, and wherever the civil hospitals were not large enough, new ones were built. The most important one was the Hôtel des Invalides in Paris. It was built for 2,500 men and was provided with 430 beds for patients, of which the surgical contingent, about a hundred and twenty, were under the care of Sabatier. The second one, the Val de Grace in Paris, with its dark and dingy rooms, left much to be desired; here there was a school where Larrey officiated, and where anatomy, physiology, medicine and surgery were taught. The hospitals were divided into three classes, according to the strength of the garrison, and were under the supervision of municipal officers and of men appointed in each community by the Committee of Safety (comité de surveillance) of the Revolution, which committee consisted of patriotic citizens. These were under the dictation of the war commissary, and cared for the welfare of the patients. In a few of the hospitals courses of instruction were given; for instance, in the newly founded school of Strasburg, twelve teachers lectured gratuitously on all the medical sciences. When a patient was taken into the stationary hospital, he received hospital clothing and his own bed, with a hair or wool mattress, or a straw sack if he soiled the bedding. The wounded were separated from those having internal disease, syphilis and scabies. Over a hundred patients were allotted to one physician and over twenty-five wounded to one surgeon, while one of the attendants, who were chosen with the greatest strictness, attended twelve patients. The surgeons could perform an operation only after they had consulted with their colleagues. They were in constant correspondence with the chirurgien en chef. Food and medicines for all the hospitals were provided through stewards and not, as formerly, farmed out, to the great detriment of the patients; only the furnishing of the beds was entrusted to the contract system. Even in the middle of the century the most of the stationary war hospitals in France were farmed out, a system in which many peculations arose, and each physician was burdened with too many patients; for the personnel of the physicians depended at that time entirely upon the contractor. The diet of the patients, under the republic, was the same as we have given in the fourth chapter for the year 1781. We should add that a sentinel was stationed in the kitchen, in order to see that no meat was taken out of the pot while the meat was cooking. As early as the middle of the century, the French soldiers received a so-called ration braid, pain de munition, which was made of flour and bran. Prisoners of war enjoyed the same fare, and if necessary an interpreter was provided between them and the physicians. Card playing and tobacco smoking were forbidden in all the wards of the hospital; at night lamps were used.

(*To be continued.*)

Operations with the Magnet on the Eyes.—The secret of success in these cases is promptness and the extraction of the iron splinter while the wound is still gaping. J. Hirschberg inspects his apparatus twice a week and tests it to have it ready at a moment's notice, and to this he ascribes his success in saving the eye in several severe cases. He prefers the Asmus sideroscope, uses cocain, and extracts the fragment with his small electromagnet, connected with a simple zinc-carbon battery, attracting a pound, combined with the large Schlosser magnet and accumulator, attracting twenty pounds. He also has on hand a still smallar magnet attracting 200 grams. Five minutes after the patient crosses the threshold, all the instruments, including the ends of the small magnets, are soaking in Schimmelbusch's soda solution, and in five to ten minutes more the iron splinter is on the table. He describes thirty-four cases thus treated, with technical success in thirty-three, in the *Deutsche Med. Woch.*, July 29, completing his record of sixty-seven magnet operations.

Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	$5.00
Foreign Postage	1.75
Single Copies	10 Cents.

In requesting change of address, give *old* as well as new location.
Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, SEPTEMBER 11, 1897.

MEDICAL MEN AND LIFE INSURANCE.

It is very evident from the large correspondence which has come to this office, that there is a widespread distrust among the profession of the methods of life insurance companies in relation to medical services. We have no desire to engage in any controversy or criticism of any company's methods of doing business, but it is clearly just to give some expression to the numerous complaints which some of the best men in the profession are making. The following incident speaks for itself: An excellent physician examined for a leading company for twenty years, receiving from three to five dollars for each case examined. On several occasions he appeared in court as a witness for the company, receiving insignificant sums compared with others; remaining away from one to five weeks at a time. His personal medical opinion was sought and given many times a year, for which he received thanks only. On one occasion he represented the company in the settlement of a case involving fifty thousand dollars, spending three days and much time in correspondence and study, for which he received as an honorarium one hundred dollars, although his services saved the company over twenty thousand dollars. Finally he took out a ten thousand dollar policy in the company, and divided the commission with the agent. His services to the company about half paid the yearly cost of the policy. Then he was taken ill and lost his little property by accident, and the company dropped him as an examiner and he failed to keep up his policy. Then he was given a paid up policy representing the amount he had paid, and finally he died. Then his policy was disputed on account of some technical error, and after a long time a settlement was made, giving less than half of the amount called for. In all this the company was legally and technically right. It was the pound of flesh, no more or no less. The services of the physician were received at the lowest rates and gratuitously, and when their interest called for it he was dropped, and his policy received the same treatment as others. A brother of this physician defended this company in a contested policy and received five hundred dollars for three days' services in court, and yet his services were inferior to his brother's testimony in the same case. A leading company, which boasts of their munificent payments of five and ten dollars for medical examination, complained bitterly and refused to pay a very competent man fifty dollars a day in a contested case.' He finally settled at thirty, although the experts on the other side were paid double this sum. While this is simply business in the commercial sense, it is the so-called liberal policy which medical directors and company managers assert so positively. The denial that companies do not encourage the aid of examiners to solicit business is contradicted in the experience of nearly all the companies. One man writes: "If it were not for the commissions from agents who share the profits with me, I would receive very little for my services." Another man writes, that while no direct bargain is made between the agent and examiner, it is expected that the examiner will suggest that his company is the best, and always advise a large policy or an increase of the present one, and receive from the agent a gratuity. Agents are always wise enough to keep up a warm interest in their company in the mind of the examiner, by presents and gratuities, and while this is not a cause for complaint, it shows that the selfishness of companies reacts and will bring its own penalties by and by.

These are only hints of the injustice and low estimation of the services of medical men by life insurance companies. There can be no doubt that the profession are responsible for this, not the companies. As long as medical men will sell their services for a mere pittance there will be buyers. Companies have no sentiment or ethics, it is simply cold selfishness – to make all the money possible, and they are ever ready to take advantage of the services of any one who will contribute to this end. The physician who fails to recognize this, and fails to demand a proper payment for his services is unwise, to say the least. One of the best physicians in the country received ten dollars for his judgment on a policy of one hundred thousand dollars. What lawyer would give an opinion on a contract involving this amount for this sum? There can be no controversy with the companies, but the profession are wrong and suicidally so. There can be no change until the physician recognizes and demands an adequate return for his knowledge, which has cost him so many years of labor and effort.

OPIUM HABIT IN CHILDREN.

Among the most decidedly bizarre statements of the report of the British Opium Commission are those anent the harmlessness of the opium habit to Hindoo children. The evidence of the report as a whole would appear to a student of the law of evidence closely akin in nature to that whereby quackish procedures are "proven" to the satisfaction of promoters of patent medicine stock companies. The inveterate opium habitué is notoriously always under an opium dream as to the harmlessness or even benefit of his habit. Propaganda for spread of opium using is often a cult with habitués. From just such persons much of the testimony in favor of opium has clearly come. The evil effects of opium on children have been publicly recognized for nearly a century. Crabbe, in that series of sociologic and medical pictures, "The Borough," sang:

> "Then the good nurse (who, had she borne a brain,
> Had sought the cause which made the babe complain)
> Has all her efforts, loving soul, applied
> To set the cry, and not the cause aside.
> She gave her powerful sweet without remorse;
> The sleeping cordial—she has tried its force.
> Repeating oft, the infant freed from pain,
> Rejected food, but took the dose again,
> Sinking to a sleep, while she her joy expressed
> That her dear charge could sweetly take his rest;
> Soon may she spare her cordial, not a doubt
> Remains but quickly he will rest without."

According to the report from 60 to 90 per cent. of Hindu infants are dosed with opium. According to one witness:

"The practice is begun in the first few weeks or months of life, sometimes even from birth, and is continued up to the end of the second or third year. The dose is usually one-sixteenth to one-twelfth of a grain to begin with and this is gradually increased to a quarter or half grain and even to one or two grains, according to the age and necessities of the child. Sometimes it is given in the form of a pill, sometimes a nursing mother smears it on her nipple. It is given partly as a remedy for the ailments of infancy, partly to keep the chid quiet. A peasant woman who has to work in the fields gives her child some opium and puts him in a basket in a corner of the hut, or perhaps she takes her child to the field and puts him in a small basket and gives him a little opium to keep him quiet. Fatalities and cases of poisoning rarely occur and it should be carefully borne in mind that this practice is discontinued usually at the third year and certainly at the fifth, and has no connection with the habit which may or may not be formed when the child is grown up."

This evidence contrasts decidedly with the results of the experience both of general practitioners and students of the opium habit. Practically the majority of these will agree with Calkins ("Opium, and the Opium Habit," 1871) in the opinion that "pestilent as is opium upon the brain developed in its maturity, yet more pernicious, times over, is the reaction when it falls upon immature years. Whether the child suck in the poison immediately through the natural, lacteal channels or whether it receives the same pure and undiluted as measured out by the teaspoon, contamination is equally assured. *Mourir en fleur ou vivre bien petit;* such is the the slippery tenure of life, such the inexorable necessity imposed. In view of such prospects what shall be thought of the fashion obtaining among families of distinction in China, that of encouraging boys yet within the age of puberty in the use of the opium pipe, with the fallacious expectation that such habit may, perchance, exert a resistive force against appetites and indulgences of a more sensual character. The furnishing of laudunum by their impoverished parents to the children employed in the cotton mills of Lancashire may make plausible show of excuse, but what can be said in palliation of practices, such as those of lace factory employes, for instance, where the infant incumbrances (fruits of the *impermissa gaudia* enjoyed in their *liaisons de convenance*) are put upon Godfrey's cordial precedent to the stronger alcoholic tincture, by which together they are used up in about six months. Dr. Harper of the Fen district, where laudunum is given extensively, states that the infant mortality is at an excessively high figure and his account is corroborated by the medical men and the clergy of parochial districts all over England.

The Fen district in England is singularly like India in its prevalent opium habit and the alleged causes for this. Opium is used in the Fens as in India for its alleged efficacy in malaria. In the Fens are seen, among other things, marked expressions of degeneracy despite the opium habit, survivals to old age of isolated members of a family, plural and frequently repeated births and a large infant mortality. On the evidence of benefit afforded by the first two phenomena, stress has been laid by the report of the British Opium Commission. They, and the fact of the survival of children from the opium habit, are brought into strong relief as proof of the sanative effects of opium. Such a style of argument clearly betrays an ignorance of the salient features of the biologic stigmata of degeneracy on the one hand and an unscientific pandering to commercialism by ignoring well ascertained facts as to the opium habit in children on the other. Levinstein (*Alienist and Neurologist*, 1883) found by experiment on pregnant dags and rabbits that the use of opium during pregnancy produced either abortion, still-births or rapidly dying offspring. Bureau later (*Progrès Médical*, July 16, 1894) ascertained that the placenta of opium-using mothers contained morphin and that this was also detected in the funis. Long ere either the experiments of Levinstein or the observations of Bureau, Drs. Calkins and F. H. Hubbard had pointed out ("The Opium Habit," 1881) that the children of opium-using mothers would die unless they were nursed by their mothers or given opium. One of his cases which excellently illustrates the features of all such is as follows:

> "A secundipara while pregnant with her third child was given morphin to secure sleep in consequence of an agonizing neuralgia. When labor occurred the amount of morphin used was 10 grains per diem. The third day after delivery her milk was suppressed to a great extent in contrast with the previous habit of the patient, who was usually galactorrheic at that time. The babe, bright and natural at birth, when placed on the bottle, became prostrate, cried, vomited incessantly and discharged a glairy mucus with meconium. The muscles twitched continuously and the babe died six days later from marasmus and insomnia. The mother increased the drug up to half a dram daily doses, which she was taking two years when a girl was born. The milk was suppressed. The babe, bright and vigorous, took the bottle readily, but soon displayed the same ominous symptoms as the last child. The mother suspecting the cause, secretly gave it two drops of laudunum. The effect was magical, all the ominous symptoms disappeared. The mother increased the dose until when the child was 7 years old, she was taking half-ounce daily doses of laudunum. She was in excellent physical health, bright but backward at school.

Similar cases were later reported by Carson Amabile, Erlemeyer, F. B. Earle, Mattison and others (*Review of Insanity and Nervous Diseases*, March, 1891). These cases readily explain the phenomena of the opium habit in children cited so exultingly by the British Opium Commission. They also reveal how potent a factor of degeneracy opium is, even on the descendants of opium-using mothers cured of the habit before puberty but remaining "backward" children, which "backwardness" in the next generation would, by the law of heredity, be transmuted into any or all manifestations of degeneracy from hemophilia, hereditary gout, hysteria, deaf-mutism, epilepsy, insanity and moral imbecility down to idiocy. The error of the British Opium Commission is that of the unscientific mind which fails to see that a given hypothesis to be accepted as correct must not only explain all the facts but must exclude all other explanations.

THE GLANDULAR FUNCTION OF THE UTERUS.

In the *Archives de Physiologie, Normale et Pathologique* for July, M. J. H. Keiffer of Brussels devotes a rather well argued article to the glandular function of the uterus; that is, to its utility in the organism as an excretory organ, eliminating toxic products in its function of menstruation. This idea is not altogether a new one, but is practically ignored in most text-books on physiology and gynecology, and the treatment of the subject in the light of modern physiology has something in it of novelty. We are accustomed of late to think of a possible extra-generative function of some of the organs of reproduction; the testicle and the ovary are supposed, with some reason, to furnish an internal secretion that has its purpose and value in the systemic economy, but the uterus is not so commonly regarded in a similar light and menstruation has been considered as a result or attendant of ovulation and therefore purely an incident of the generative function, perhaps a quasi-pathologic result of a somewhat abnormal human evolution. The glandular structure of the uterine mucosa has been credited with merely furnishing the needed mucous secretion of such an internal cavity suited to its special reproductive function.

The disturbances noted as following disorders of the menstrual function are many of them such as would naturally suggest an auto-intoxication, but it has been customary rather to refer them to some obscure reflex influence than to poisoning by retained products, notwithstanding the fact that an actual excretion normally occurs. M. Keiffer's argument is based on an experimental study of the relations of the muscular and vascular apparatuses and the mucosa, his observations having been made both on the human female and experimentally on the dog in the condition of rut, and he finds that while the arrangement of blood vessels is such as to indicate that the nutrition of the epithelial tubes of the uterine mucous membrane is of the very first importance, the function of the latter does not seem to be exclusively limited to the production of mucous or mucin. There is, as was well known before, though its importance has perhaps been underestimated, a decided chemical alteration in the menstrual blood—it does not clot like ordinary blood, and he maintains that the uterine epithelium acts here like the kidney glomerule and that fibrin passing the one is analogous to albumin passing the other. Charrin (*Gazette hebd.*, Jan. 3, 1896) has shown that the blood is at its maximum of toxicity at the menstrual period, and that disordered menstruation has its affect upon other secretions, infants at the breast being affected by such conditions in their nurses. The menstrual process, M. Keiffer holds, acts in two ways, preparing for the maturation of germinative elements and exciting genetic activity on the one hand, and on the other eliminating from the organism certain products of secretion that failing their direct bio-chemical application in reproduction must be rapidly discharged. If this elimination fails, if these products are not utilized or gotten rid of, they acquire a toxic property and their reabsorption gives rise to the disturbances of the nutrition and the derangement of systemic equilibrium that we observe as the effect of disordered or suppressed menstruation; the vascular, secretory, digestive and psychic disturbances that are generally and rapidly relieved by the re-establishment of the function in its full normal activity. Menstruation has been called a disappointed pregnancy, and in this point of view it is easy to see how the results of such will need to be gotten rid of in the normal economy of the organism. The uterus is in that sense certainly an excretory organ during the whole reproductive life, and the disturbances of the menopause are the results of an auto-intoxication from products to which the system only gradually becomes more accustomed and tolerant, until finally, with the suppression of the genetic function, they cease to be produced. The influence of the ovarian internal secretion can not well be invoked to account for auto-intoxication symptoms, such as many of those of the menopause and those accompanying menstrual suppression and disorder seem to be. Chlorosis, with which menstrual disorders generally seem to be associated, often in a causal way, may also possibly be properly considered as, in part at least, a symptom of uterine auto-intoxication according to this theory of the uterus as an excreting glandular organ, and certain anemic disorders following parturition may possibly also fall into the same category.

It has heretofore been the custom to attribute all or many of these disturbances in the economy to a reflex influence from the genital organs, an easy but not very definite method of explanation. If we adopt the theory here proposed, that throughout the sexual life of women there is a constant contribution, it may be from all parts of the organism, of material destined for reproductive purposes, which failing its normal function must be thrown off through the process of menstruation, and which if retained causes promptly the symptoms of intoxication of the system, we have at least advanced a step beyond the mysterious and ill-defined "reflex influence" that has hitherto been invoked. The theory certainly has some merits and some facts apparently to support it, and it is, at all events, one that is suggestive and worthy of some consideration.

THE LIMITATIONS OF SERUM DIAGNOSIS.

While the preponderance of evidence thus far accumulated is in favor of the specificity of serum reactions the time is not yet ripe for a final conclusion upon this important subject. It certainly were a great gain if the diagnosis of diseases dependent upon isolable micro-organisms could be always established with certainty by this means. In many cases the test would not be necessary, but there remains a considerable number in which doubt exists from beginning to end. It is especially in these, and for hygienic and prophylactic reasons, that a reliable if not an infallible means of diagnosis would be of the greatest practical utility.

M'FADYEAN (*Journal of Comparative Pathology*, December, 1896) found that the blood serum from a case of glanders in the horse caused well-marked agglutination of glanders bacilli in bouillon culture, and FOULERTON (*Lancet*, May 1, 1897, p. 1201) has now made a similar observation in a case of glanders in man. In testing the serum a bacillary emulsion was made by adding five c.c. of a 0.5 per cent. solution of sodic chlorid to a five days old culture of the bacillus on glycerin-agar. The contents of the tube were shaken up gently and then allowed to stand for about an hour in order that any small particles visible to the naked eye might settle. The upper part of the fluid was then pipetted off and the emulsion thus obtained was found to be in every way suitable for the experiments. The bacilli used were of a stock isolated from pus derived from the patient in question. In hanging-drop preparations in which the proportion of serum to bacillary emulsion was one part to nine, large clumps always formed before the specimen could be transferred to the stage of the microscope for examination. With one part of serum to nineteen of the emulsion agglutination invariably occurred within ten minutes. The agglutinative action of the serum was equally well shown in test-tube experiments. Samples of normal human serum used in the proportion of one part to nine of the emulsion caused no change whatever in the bacilli, whether in hanging-drop preparations or in test-tubes.

On repeating the foregoing experiments with a similar bacillary emulsion, but substituting for the glanders serum antidiphtheric serum and also serum from cases of typhoid fever, equally well-marked agglutination of the glanders bacilli took place. Similar results were also obtained with bouillon-cultures of the bacilli, control experiments being carried on throughout. On reversing the experiments it was found that a certain though decidedly less active agglutination of the typhoid bacillus was caused by both antidiphtheric serum and glanders serum.

These observations, if confirmed, would render doubtful the value of the serum reaction in glanders as an aid to clinical diagnosis. In conclusion, the opinion is expressed that it is most unlikely that the unknown substance which in the serum of typhoid fever, for example, exerts so potent an influence on the typhoid bacillus should be inert as regards other bacteria. It should, therefore, not be surprising that the equally unknown but probably similar substance in antidiphtheric serum has an agglutinative action on the bacilli of both glanders and typhoid fever.

CORRESPONDENCE.

Klondike Nosology.

CHICAGO, Sept. 6, 1897.

To the Editor:—The editorial in the JOURNAL of August 28 headed "Klondike Nosology," recalls to me certain experiences in Alaska that might possibly supplement those of Dr. Rosse. His personal knowledge of the Alaskan climate appears to have been derived from summer trips upon government vessels, which in a country where winter reigns nearly two-thirds of the year, could hardly afford a perfectly adequate conception of all its phases and possibilities.

My own experience with that region dates back to a period considerably anterior to my medical education, but I can, notwithstanding this fact, recall some observations that in the light of subsequently acquired knowledge, may have some medical value. A brief summer sojourn would have given me a very different notion from that I actually obtained as to the climate and its effects.

Dr. Rosse makes but the briefest mention of the one disorder that is, I think, the most to be feared by those going into the country, at least where there is any possible predisposition to its occurrence, viz., rheumatism. I have seen both natives and whites disabled by it, and one of the worst cases of chronic rheumatism I have ever seen was in a Sitka Kaloshan Indian who had been transferred to the lower Yukon region. I have no doubt that many of those who spend one or more winters in the country will date troubles of this kind from that sojourn.

Scurvy is mainly a preventable disease, but a taint of it is likely to follow the long darkness and monotonous diet of an Arctic winter, and it is possibly from this that an exception I have noticed to Dr. Rosse's statement as to the healing of wounds, orignates. In men apparently in robust health, and conscious of no bodily ailment, I have seen the slightest scratch become a festering sore, requiring weeks for perfect healing. A slight cut of the finger would sometimes become a wide crack extending almost to the bone and this apparently without suppuration or causing severe pain, or great inconvenience to the sufferer. This occurred when what was thought to be reasonable care was taken as to cleanliness; neglected wounds followed pretty much the same course, according to my observation, as elsewhere, though I can recall no cases of erysipelas or other malignant process. Sloughing and suppuration were common enough after severe frost bites even when under good care. Among the Eskimos there certainly ought to be no lack of bacteria, and one of their common treatments of wounds was an application of a generally utilized liquid, stale urine, which from its strong ammoniacal nature seems to saponify the oily deposits upon the skin and thus tend rather to cleanliness. It should be added that they usually finished the treatment with ablutions of clean water and the general effect upon the intact skin was good rather than otherwise.

Alcohol may be one of the best antiscorbutics in summer, but I should disagree with Dr. Rosse as to its value in the far north in winter and doubt whether the quality of the liquor would have much difference on the natives. In the case of the St. Lawrence islanders, I have heard that the depopulation was mainly due, not directly to the alcohol, but to starvation following the debauches. They neglected to lay up their supplies and died in consequence, and it would have made little difference whether they were drunk from the meanest rot-gut or the best Hennessey brandy. I should say here that the Eskimo is the only North American aborigine that I have ever seen go deliberately into the retail liquor business, dealing out the drink to his fellows and abstaining himself. I doubt whether any other native would have such self-control under the constant temptation. They are born traders, however, and a keg of whisky well watered is one of the most profitable stocks in business, so one temptation probably balanced the other. They are as Dr. Rosse says, subject to colds and lung troubles and the epidemics of civilization have been especially fatal. I have heard of deserted villages from smallpox, and undoubtedly the grippe has had its run amongst them. Other disorders which they seemed especially subject to were mild ophthalmia, possibly originating in snow blindness or in their smoky huts, and various skin diseases; favus is one that I can recall. Syphilis and gonorrhea appeared to be rare at that time, but may be more prevalent now.

I can agree with what Dr. Rosse says as to their intelligence and capacity, but that has been remarked by many observers.

One thing remains to be mentioned, that is the depressing influence of the long winter darkness upon many who experience it. I have known of several cases of insanity probably from this cause, and at least three suicides. It is possible that there will be many cases of this kind in the Klondike crowds next winter, and I can say that the extreme north is not the best region for those who have a melancholic predisposition. Aside from this, and the dangers of rheumatism, scurvy, starvation, subsequent lung disorders, snow blindness, freezing etc., the far north is a fairly healthy latitude. Malaria, as Dr. Rosse remarks, has been observed on Cook's Inlet, and I have seen a Finlander suffering from what was apparently chills and fever after sleeping out in the tundra at St. Michaels in the month of May. A healthy man from a warm or temperate climate, with plenty to eat and wear, good shelter and cheerful company and surroundings and who keeps clean and who takes plenty of exercise, will generally stand his first winter well. He may find subsequent ones less comfortable, and it is quite possible that after his return to warmer latitudes he may have some reminder of his northern experiences in the way of rheumatism, lung troubles, etc. Of course this does not apply to men of especially rugged physique, but it is likely to be true of a large class of average individuals, and especially so with those who have any predisposition to such ailments.

Of the Klondike region itself I have had no experience, my personal knowledge of Alaska being mainly confined to the coast and lower Yukon district, like that of Dr. Rosse himself. But notwithstanding certain climatic differences that must exist, the perils to life and health must be in the main the same in both regions; what is true in this respect of the one is probably true also of the other.

Very respectfully, H. M. Bannister, M.D.

Dr. Upshur's Final Reply to Dr. Woodbridge.

Richmond, Va., Aug. 23, 1897.

To the Editor:—I had hoped not to trespass upon your valuable space further, but the offensive communication from Dr. Woodbridge in your issue of August 21 can not be passed unnoticed. Now, sir, it can not be possible that Dr. Woodbridge is ignorant of the fact that Messrs. Parke, Davis & Co. are advertising Woodbridge treatment of typhoid fever, and will send the literature to any one who applies for it. The pamphlet referred to contains liberal extracts from the several papers read by Dr. Woodbridge and refers to the source from which taken, therefore must be the genuine utterances of Dr. Woodbridge. Why does he permit this wholesale drug house to put him in so equivocal a position? Does he deny that the statements made in this "advertising circular" are genuine? But, sir, there is no need of examining the circular, his paper published in the July 10 number of the Journal is identical in style, statement and "*testimonials*" with the pamphlet. Now this word seems to be especially offensive to the Doctor. Let me say to him they are like the other testimonials referred to in being mere bald assertions, not proven from a scientific standpoint. The Doctor is kind in suggesting a title for my paper; had I had the honor of his acquaintance before the meeting of the Association no doubt it would have been adopted. He ridicules my quotations from the circular—it is *his circular*, or *purports to be*. The *Doctor's valuable lecture* on disinfection I will lay to heart and when opportunity occurs it shall be applied to his *manners*, which his communications show need purifying. He evidently does not know how a gentleman should con[illegible] a scientific c[illegible] that there is no justification or excuse for the utterance of a libel on the personal character of his opponent. I would advise this very progressive M.D. to buy some modern works on practice and study the pathology of typhoid fever; I think *even he* can learn something from Tyson, Osler, Wilson, Wood & Fitz and a number of other *modern* works on practice. In criticizing me he has no right to ignore the authorities I quote to sustain my position. I *had not* been a member of the ASSOCIATION only a "few hours" when I read my paper and would remind him that the cordial reception it received showed it had the approval of the Section. My time expired and a motion for its extension was unanimously carried. The statement that I have violated the written or unwritten law of the profession is in no sense true. What egotism for Dr. Woodbridge to arrogate to himself and endorsers that they are *the* medical profession. He distorts what I say to further his own argument. I do not wish it understood that good men are lacking in a true appreciation of the responsibility in the care of typhoid fever, but it is true that men trying conscientiously to do their duty fail to make accurate observations. I am glad to accord to my professional brethren all the courtesy which belongs to them in the report of medical facts or results, but I have a right to demand a reason for the hope that is in them and ought not to be required to take what is said on blind faith. No, not even from so absolutely an infallible man as the Doctor himself. I am sorry the Doctor has not the circular referred to; I have always found Messrs. Parke, Davis & Co. most courteous to the profession and I am sure they will supply the Doctor with one if he will write for it. He will then, after examining it, have an opportunity to forbid its *farther circulation*, if he desires (?).

Respectfully, J. N. UPSHUR, M.D.

The Antivivisectionists.

August 30, 1897.

To the Editor:—In your recent editorial entitled, "The Antivivisectionists and Their Little Bill," you allude to the appellation "of degenerates or perverts" being applied to those who are in favor of restriction of vivisection.

There is a larger number of the medical profession in favor of the antivivisection bill than its opponents suppose and they won't be "muzzled" by being called by revolting titles.

It is no more a convincing argument to liken humanitarians to weak-minded members of the criminal classes than it would be a just retort for them to claim that those most actively engaged against Senate Bill No. 1063 were men who simply desired to slaughter their thousands of dumb animals as a means of professional advertisement.

I beg to enter my protest, therefore, against what I consider an attempt to suppress free expression of opinion from the humaner members of our most noble profession through the creation of a false sentiment against them, as well as by the false statement of facts pertaining to the above-mentioned bill. E. O. N. K.

ANSWER:—In our remarks on the subject we were very far from saying that all antivivisectionists were perverts; we only said some of them were, and cited instances. There are no doubt many excellent persons in this movement who are simply misguided.

The Maker of a New Instrument.

AURORA, ILL., Sept. 2, 1897.

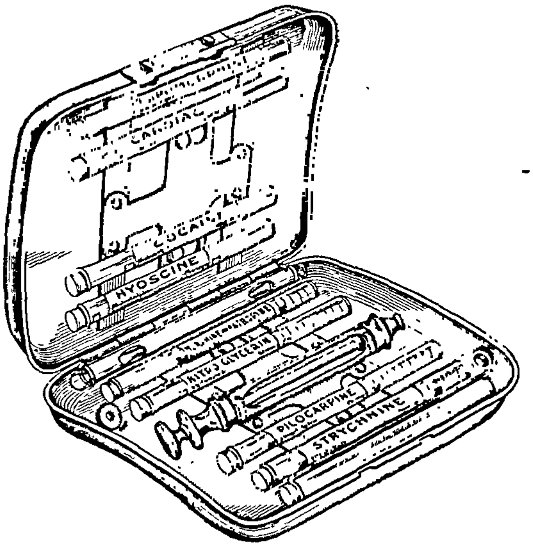
To the Editor:—Since the publication of my article in the JOURNAL on "A New Curette," I have been in receipt of numerous inquiries as to where the instrument is made. A footnote in the original article stated that it was to be made by Sharp & Smith, but, I presume from some oversight, was omitted. I shall deem it a great favor if you will make a note as to who the makers are in the next issue of the JOURNAL.

Sincerely, C. L. SMITH, M.D.

NEW INSTRUMENTS.

AN IMPROVED HYPODERMIC SYRINGE.

The accompanying illustration shows one of the latest improvements in the hypodermic syringe. The case is of aluminum and is curved to fit the body when carried in the vest pocket. It may be sterilized by boiling. The piston packing is of rubber and is greatly superior to asbestos which shreds, and to leather which has a tendency to harden. The packing may be speedily renewed by any one. This case was designed by the Mulford Company and is supplied with two reinforced needles and eight tubes of selected hypodermic tablets.



SOCIETY PROCEEDINGS.

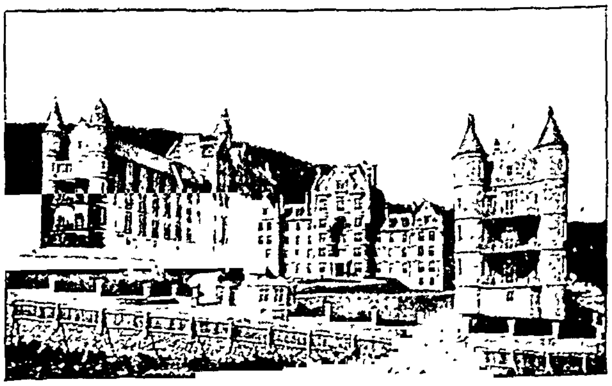
British Medical Association.

Sixty-fifth Annual Meeting, held at Montreal, Aug. 31 to Sept. 4, 1897.

T. G. RODDICK, M.D., M.P., Professor of Surgery in McGill University, Montreal, presiding.

The opening service of the Association was a sermon at the English Cathedral, St. Catherine Street, by the Right Reverend the Bishop of Niagara (Dr. Dumoulin) at noon, Tuesday, August 31.

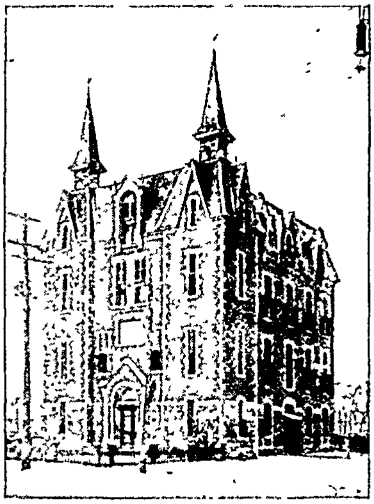
The opening ceremonies in the afternoon were held in Windsor Hall. The chair was occupied by the President of Council, Dr. Saundby, in the absence of Dr. Roddick, the President of the Association. In addition to the members of the Council of the Association; the Governor-General of Canada (the Earl of Aberdeen); the Lieutenant Governor of the Province of Quebec, Sir Adolphe Chapleau; the Mayor of Montreal; the Right Hon. Lord Lister and the Right Hon. Lord Strathcona and Mount Royal occupied places on the platform. Dr. Saundby



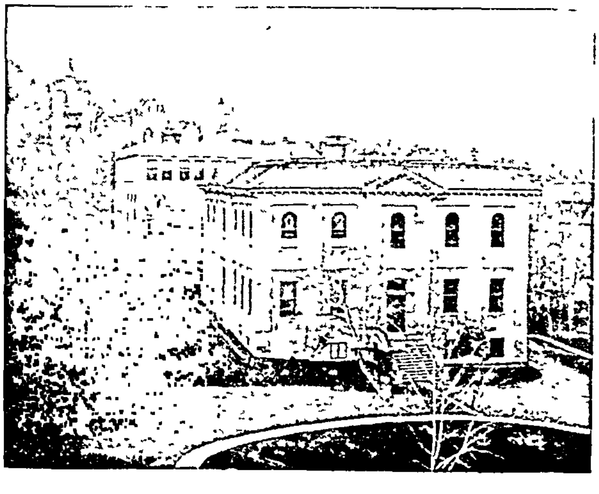
ROYAL VICTORIA HOSPITAL, MONTREAL.

spoke of the unusual circumstances of the meeting of the Association, as it had never before been held outside the British Islands, making the Montreal meeting an adjourned meeting, the first part of the annual meeting for 1897 having been held in London, July 27, in order to comply with the obligations imposed on the Association by statute and by its by-laws.

Dr. Roddick, taking the chair, introduced the Mayor of Montreal, who, welcoming the Association to the city of Montreal, spoke of the appropriateness of holding the first meeting of the Association outside the British Islands in the Dominion's metropolitan city and in a British colony under a colonial president, thus showing that the Association was not of Great Britain but of Greater Britain. He believed that nowhere in the sovereign's vast dominions had the Diamond Jubilee been celebrated with more loyalty or with more enthusiasm than in Montreal, as there, French-Canadians, Irish, Scotch, English and other nationalities, of varying creeds, vied with one another to do honor to themselves in honoring their world-honored sovereign. He spoke of McGill, Laval and Bishops Universities and other educational institutions of Montreal, and their living monuments to the names of such men as Lord Mount Stephen, McDonald, Redpath, Morris, Galt and others. Reference was made to the erection of Royal Victoria Hospital, which stands at the foot of Mount Royal, by the munificence of Sir Donald Smith and Lord Mount Stephen; Montreal General Hospital, the oldest hospital in the Dominion; Notre Dame Hospital; the Western General and other such institutions which give Montreal first rank in proportion to her population and size, so far as regards her institutions.



WESTERN GENERAL HOSPITAL, MONTREAL.

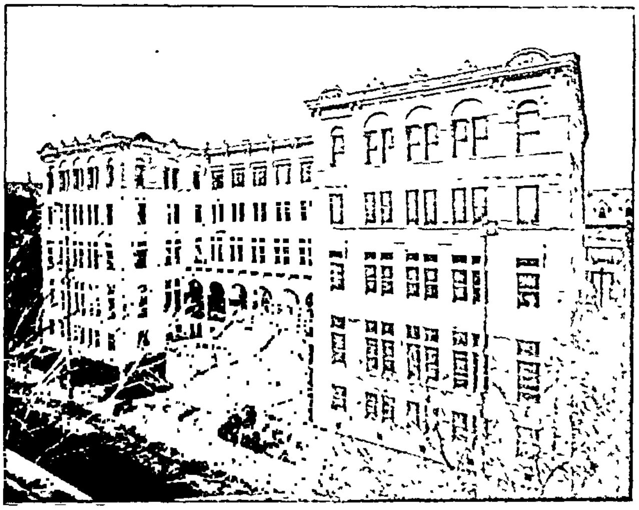


THE MEDICAL COLLEGE, MCGILL UNIVERSITY, MONTREAL.

Sir Adolphe Chapleau welcomed the Association in behalf of the Premier of Quebec, extending to them the freedom of the province, as every citizen was ready to extend to them the freedom of the country.

The Governor General of Canada (Earl of Aberdeen) gave the third address, welcoming the Association in the name of the Dominion.

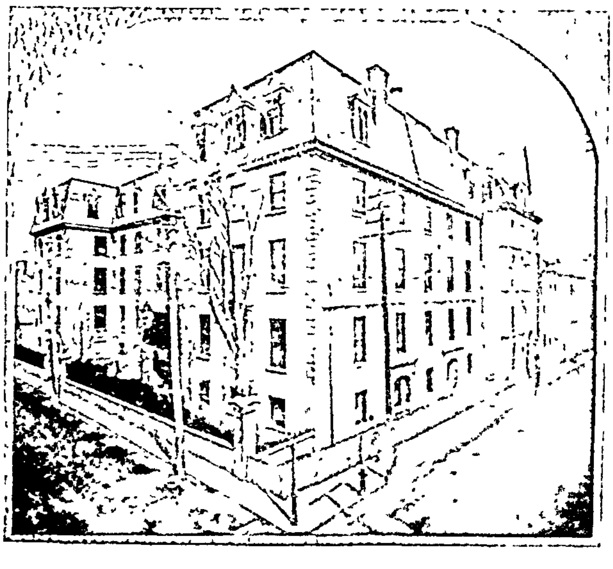
After the roll of delegates of foreign countries and medical societies was called and those in attendance were formally presented to the President and the Governor General, the presidential address was delivered by Dr. Roddick on:



LAVAL UNIVERSITY, MONTREAL.

CANADA, ITS MEDICAL LIFE AND RESOURCES.

He made many apt references to the distinguished guests; Lord Lister, the most illustrious surgeon of our generation; the representative of La Belle France, Dr. Charles Richet, professor of physiology in the University of France, and others.



MONTREAL GENERAL HOSPITAL.

He traced the history of the British Medical Association from its organization in 1832; went into detail concerning Canadian climatic conditions, the health resorts, the effect of the Canadian climate on European races, Canadian Spas, medical education in Canada, nursing, medical legislation in Canada, etc.

On motion of Lord Lister a vote of thanks was extended the speaker, after which Dr. Saundby expressed the obligations of the Association to the Governor-General, Lieutenant Governor Chapleau

In the evening a soirée was given at Laval University; an address by Professor Richet, official Representative of the French Government (to be published in the JOURNAL at an early date); and a reception by the Governor-General.

WEDNESDAY, SEPTEMBER 1.

The morning was devoted to section meetings at McGill University.

At the afternoon session the "Address in Medicine" was delivered by WILLIAM OSLER, M.D., F.R.C.P. (*vide* p. 507). The meeting was then converted into a convocation of McGill University and the degrees of LL.D. conferred on the following: The Right Honorable Lord Lister; Dr. Charles Richet; Sir Walter Foster; Sir William Turner; Dr. Henry Barnes; Prof. Michael Foster; Dr. W. H. Gaskell; Mr. Christopher Heath; Dr. Alexander Macallister; Dr. R. Saundby and Claud Wheelhouse.

The remainder of the afternoon was occupied by a garden party given in the grounds of the Royal Victoria Hospital, and the evening by a reception by Lord Strathcona and Mount Royal.

THURSDAY, SEPTEMBER 2.

The morning was again taken up with section meetings.

At 1 P.M. the Association and its guests were tendered a luncheon on Mount Royal, by the Mayor of Montreal. Following this the address in surgery, "The Surgeon of Old in War" was delivered in Windsor Hall, by Mitchell Banks, F.R.C.S., of Liverpool (to be published in the JOURNAL at an early date).

An international golf match, garden parties, and the laying of the foundation stone for the Nurse's Home at Montreal General Hospital, occupied the remainder of the afternoon. In the evening the annual dinner of the Association was given at the Windsor Hotel, and a concert at Windsor Hall.

FRIDAY, SEPTEMBER 3.

Section meetings, as usual, occupied the morning hours. The afternoon session was taken up by an "Address in Public Medicine," by Herman M. Biggs, M.D., Director of the Bacteriologic Laboratory of the Health Department of New York City. The address covered a wide field, was well received and contained much detailed information of the bacteriologic work of the Health Department of a great city, more valuable as giving the members of the Association an insight into the workings of one of our American cities.

After the address an invitation was extended the members of the Association, by the American Public Health Association, to be present at their twenty-fifth anniversary in Philadelphia, Oct. 26 to 29, 1897. The evening was taken up by a Conversazione at McGill University.

SOCIETY NEWS.

The Tennessee State Medical Society will meet next year at Jackson. The officers are W. D. Haggard, M.D., Nashville, Secretary; T. K. Powell, M.D., Dancyville, President.

The French Congress of Alienists and Neurologists was held at Toulouse in August, in honor of Pinel and Esquirol, the pioneers of the modern humane treatment of the insane in France. Esquirol's maxim was: "One must love the insane to be worthy and capable of serving them." Busts were installed in the capitol, similar to the statues already erected on the scenes of their labors, the Salpêtrière, Paris, and at Charenton. "The Diagnosis of General Paralysis" was the subject of the first address, by Arnaud, who described the dual orders of symptoms as: Physical, *i.e.*, troubles in speaking; the gradual and progressive internal ophthalmoplegia; psychomotor ataxia and cerebral accidents. 2. Mental, *i.e.*, the generalized and progressive dementia, evidenced by the lack of mental power, by the absurdity of the mental operations, association of ideas, reasoning, judgment, rather than by the absurdity of the ideas themselves; by the gaps in the memory; by the change in the moral sense, and in the conduct and actions. In certain cases of congestive insanity and pseudoparalysis it is impossible to differentiate at first, and also in the prodromic period while general paralysis may be suspected, there are no positive signs to establish the diagnosis. After 55, general paralysis is extremely rare. With a patient over 50, showing signs of arteriosclerosis, we must remember that generalized cerebral atheroma may simulate clinically general paralysis, or may be associated with it. True hemiplegia should also impose a doubt, as the probability of general paralysis is slight in that case, and some other pathologic condition certainly exists. Blindness opposes rather than favors the diagnosis of general paralysis. If the affection has developed rapidly, or after an infection (syphilitic) or toxic condition, and if there is alcoholism, it is best to wait for further developments before diagnosing. Others dwelt upon the relations between alcoholism, syphilis and general paralysis, for which they prepare the soil. Professor Mossé reported a case of an unknown disease, still undescribed; a neurofibromatosis of the cerebellum and base of the encephalon. Bézy's address on "Infantile Hysteria" is given in full in the *Progrès Méd.* of August 7. He agrees with Pitres that the hysteric child *nascitur non fit.* Neuropathic antecedents, scrofula, tuberculosis, gout, have all been signaled in the etiology. The manifestations develop according to the education, emotions and contagion. Traumatism and conditions of the prepuce requiring surgical intervention have also caused it to develop, even in very young children (Bosc, infant, eighteen months). Infective diseases have also aroused it.

The International Medico-Legal Congress, Brussels, August 2 to 7.—The following recommendations were adopted after addresses and much discussion of the subject of the criminal insane: 1, the establishment of a special asylum by the State for the criminal insane; the judicial authority alone to be the arbiter of their confinement; 2, the confinement can only be terminated by decree of the judicial authority, and only when the morbid affection is considered positively cured and free from all probability of a relapse. The judicial authority may decree the release provisionally and under certain conditions; 3, the decree of release from confinement to be revocable whenever the mental condition of the patient inspires serious fears of a relapse; 4, every convict who becomes insane to be confined in a special asylum, or at least in a special quarter of an asylum; 5, these measures are to apply also to those individuals convicted of a crime or misdemeanor whose penalty has been attenuated on account of their mental condition. If confinement is necessary when their term of punishment expires, it shall be decreed by the jurisdiction in which they were tried. Numerous telling examples showing the necessity of these recommendations were described; among them we note the case of a parricide recently acquitted in Paris, on the ground that he was an "impulsive," who at once resumed his occupation of a barber. Dr. Norman Ken's address on the "Legal Responsibility of the Drunkard" was repudiated by the Congress in so far as it admitted the excuse of irresponsibility for drunkards. "Intoxication by Carbonic Oxid" was presented by Bergé and Nobele, while Brouardel, Vleminckx and Depaire joined in the discussion. The Congress finally adopted the conclusions: 1. Death from carbonic oxid is very frequent and often fails of recognition. 2. This intoxication rarely occurs alone, but is usually associated with other gases, which accounts for the variety of phenomena observed. 3. It is rarely used with criminal intent and death from it is usually accidental, although the number of suicides from it is quite large, especially in France. 4. The duration of exposure is as important a factor as the amount inspired. 5. The smallest proportion prejudicial to health is 0.05 per cent. 6. Intoxication is possible when the gas is still not sufficiently concentrated to extinguish a lamp. Intoxication from illuminating gas is also possible when the concentration is not sufficient to produce an explosion in contact with flame. 7. Complete saturation of the blood with carbonic oxid is not possible during life. It has never passed beyond 79 to 80 per cent. 8. Death from carbonic oxid is not always accompanied with a lowering of the temperature. 9. Sugar has frequently been noted in the urine of persons intoxicated with it. 10. The diagnosis of intoxication from this cause is based principally on the spectroscopic and chemic examination of the blood, but the characteristic indications in the blood may be entirely absent if, in addition to the CO, the inspired air contained also another gas, carbonic acid for instance. 11. The time of its disappearance from the blood is still undetermined. Pouchet has observed it still present sixty hours after the intoxication. 12. The differential diagnosis between intoxication from carbonic oxid and from illuminating gas is very difficult, and neither chemic analysis nor the anatomo-pathologic changes are sufficient to distinguish these two modes of intoxication. Study of the accompanying circumstances can alone decide. 13. Carbonic oxid is unique in its action on the hemoglobin, preventing the passage of the oxygen to the tissues, and it has still another special effect, evidenced by the facts: 1. That the symptoms of intoxication from it differ from those of simple asphyxia. 2. That serious symptoms appear before the blood contains enough of the CO to allow them to be ascribed to the asphyxia. 3. Intoxication from it is followed by profound disturbances in the nervous system, also by trophic disturbances in the skin and intestines, which can not be ascribed to simple asphyxia. 4. It can also lead to chronic intoxication characterized by globular anemia accompanied by disturbances in the general nutrition. The question of medical secrecy led to long discussion, in the course of which Brouardel remarked that when there is a medical secret it should be absolute, but that many things in medicine are not secret and others only occasionally secret. He added that the physician's declarations of death in France do not reveal the name of the deceased, and that the persons who receive the declarations of contagious diseases are sworn to secrecy and keep their pledge. The question was finally referred to the next International Congress, Paris, 1900, expressed as follows: The physician should have the right to invoke his professional secrecy in regard to the facts learned by him, in the exercise of his profession, concerning a person who is, might be or might have been implicated through these facts in some legal or criminal proceedings, or affected in his honor or reputation. Other subjects discussed were "Subserous Ecchymoses," "Internal Factors in the Putrefaction of Bodies," "Docimasia Pulmonum," "Intoxication from Meat," and "Hypnotism and Criminality." The attendance was not so large as expected, but was thoroughly international and will prove to have hastened the day when the great science of forensic medicine, requiring such encyclopedic knowledge and experience, will receive due recognition and support from the state.

Mississippi Valley Medical Association.—Arrangements are now about completed for the meeting of the Association at Louisville on Oct. 5–8, 1897. The different passenger associations have granted a round-trip rate of one and one-third fare on the certificate plan. The sessions will be held at the Liederkranz Hall, and the headquarters will be at the Louisville Hotel. The following are among those whose papers have been accepted:

J. B. Murphy, Chicago, Address on Surgery; J. V. Shoemaker, Philadelphia, Address on Medicine; I. A. Abt, Chicago, The Nature of Croup following Measles; J. C. Ayers, Cincinnati, Further Observation in the Use of Hydrogen Dioxid in the Treatment of Blepharitis Marginalis; W. F. Barclay, Pittsburg, Milk, Its Production and Uses; J. F. Barnhill, Indianapolis, Regarding Hypertrophied Faucial Tonsils; J. M. Batten, Pittsburg, Report of Five Cases of Heart Disease; J. K. Bauduy, St. Louis, Some New Thoughts in the Treatment of Locomotor Ataxia; A. C. Bernays, St. Louis, Paper; A. F. Bock, St. Louis, The Surgical Treatment of Basedow's Disease; John Young Brown, St. Louis, Some Remarks on Appendicitis; Sanger Brown, Chicago, Some Anomalous Conditions of the Spinal Cord, with Report of Cases; Eug. G. Carpenter, Cleveland, Posterior Radicular Neuritis; W. Cheatham, Louisville, Of what Assistance has the Serum Treatment of Diphtheria been to the General Practitioner; Archibald Church, Chicago, The Differential Diagnosis and Treatment of Cerebral Hemorrhage and Cerebral Softening; J. W. Cokenower, Des Moines, Iowa, Neurotic Deformities in Children; A. H. Cordier, Kansas City, Ectopic Pregnancy, Clinical and Pathologic Phases; J. Homer Coulter, Chicago, Paper; Ephraim Cutter, New York, Beef—A War Paper; Richard Deway, Wauwatosa, Wis., Some Cases of Insanity in Adolescence; Arch Dixon, Henderson, Ky., To Drain or not to Drain; Kennon Dunham, Cincinnati, The Hypodermic Syringe and Its Use in Malaria; C. Travis Drennan, Hot Springs, Ark., Report of a Case of Anesthesia Produced by Mercury, with Remarks; Sherwood Dunn, Los Angeles, Mothers and Daughters; J. Rilus Eastman, Indianapolis, Diagnosis by Inspection in the Urinary Tract; A. R. Edwards, Chicago, The Diagnosis of Abscess of the Liver based upon a Study of Twenty-five Cases; Jos. Eichberg, Cincinnati, Typhoid Fever Treated Without Cold Baths; C. Fisch, St. Louis, The Antitoxic and Bactericidal Properties of the Serum of Horses treated with Koch's New Tuberculin (T. R.); F. R. Fry, St. Louis, Pressure Symptoms After Head Injuries; A. H. Goelet, New York, The Surgical Treatment of Fibroid Tumors of the Uterus; Spencer Graves, St. Louis, Appendicitis; H. Hatch, Quincy, Ill., Severe Injuries from Electricity and What Best to Do; A. G. Hobbs, Mouth-breathing in Children; discussion opened by Dr. H. W. Loeb; B. W. Holliday, Cleveland, The Civic Aspect and Therapy of Some of the Common Neuroses; A. F. House, Cleveland, Symptoms and Surgical Treatment of Perforated Intestinal Ulcers; W. H. Humiston, Cleveland, Ohio, Cocain Anesthesia in Perineorrhaphy; C. C. Jacobs, Frostburg, Md., The Treatment of Obstructive Lesions of the Urinary Tract, Anterior to the Bladder, with Especial Reference to the Enlargement of the Prostate Gland; A. C. Klebs, Chicago, Paper; E. L. Larkins, Terre Haute, Ind., Appendicitis; F. F. Lawrence, Columbus, Ohio, Hysterectomy; Elmer Lee, New York, The Elimination of Empiricism in the Treatment of Pneumonia; I. N. Love, St. Louis, The Relations of the Secular Press to Medicine and the Public; C. F. McGahan, Aiken, S. C., The Treatment of Pulmonary Phthisis; A. H. Meisenbach, St. Louis, A Plea for Early Operation in Cholelithiasis; L. Harrison Mettler, Chicago, Neuroses of Gout; Robt. T. Morris, New York, Paper; Harold N. Moyer, Chicago, Paper; A. M. Owen, Evansville, Ind., Cathartics and Constipation; A. J. Ochsner, Chicago, Treatment of Hernia in Old Men; Curran Pope, Louisville, Ky., Sanitoriums a Necessary Factor in the Treatment of Chronic Diseases; Joseph Price, Philadelphia, Paper; J. Punton, Kansas City, The Growing Needs of Medical Political Organization; D. C. Ramsey, Mt. Vernon, Ind., Municipal Sanitation of Tuberculosis; A. Ravogli, Cincinnati, Tuberculin in Dermatology; B. Merril Rickets, Cincinnati, Abdominal Incision for Ascites; Byron Robinson, Chicago, The Classification of Peritonitis; Enno Sander, St. Louis, The Carlsbad Springs of the United States of North America; E. W. Saunders, St. Louis, Therapeutic Properties of Infant Foods; E. J. Senn, Chicago; The Treatment of Suppurating Fistulous Tracts; E. B. Smith, Detroit, Experimental Surgery; J. O. Stillson, Indianapolis, Retro-bulbar Optic Neuritis; L. Strauss, St. Louis, Primary Tuberculosis of the Rectum with Report of Cases; J. A. Stuckey, Lexington, Ky., Intratympanic Surgery in Chronic Suppuration; J. B. Taulbee, Mt. Sterling, Ky., The Treatment of Wounds by the Open Method; H. M. Thomas, Chicago, Experimental Work of the Penetrability of Vaporized Medicaments in the Air Passages; K. K. Wheelock, Fort Wayne, Ind., Plastic Operation for Reforming Interpalpebral Space; Alex. C. Wiener, Chicago, Congenital Dislocation of the Hip; Frank Woodbury, Philadelphia, Paper.

Titles of papers should be sent to Dr. Thomas Hunt Stucky, President, Louisville, or to Dr. H. W. Loeb, Secretary, St. Louis.

BOOK NOTICES.

Transactions of the Medical Society of the State of New York for the year 1897. Cloth, 585 pages. Illustrated. Published by the Society, 1897.

The work is well edited, well bound and on excellent paper. The contents comprise reports of committees, of list of members in attendance at the 1897 meeting, minutes of the proceedings, obituaries, lists [illegible] the Society from [illegible] organization to the [illegible] conditions of bility to membership, county medical societies and incorporated voluntary medical societies with forty-six papers, many of them of great value to the practitioner.

Transactions of the Sixth Annual Meeting of the American Electro-Therapeutic Association, held Sept. 29, 30 and Oct. 1, 1896, at Boston, Mass. Cloth, 140 pages. Illustrated. Published by the Association.

Lists of officers, honorary fellows, fellows and associate fellows, committees and the Constitution and By-Laws occupy sixteen pages. The remainder of the text is taken up with the "Proceedings of the Sixth Annual Meeting," including many papers of interest and value. An appended chart is so arranged that the reader can instantly note the symptoms, treatment, results, etc., of the cases referred to in the various papers.

First Annual Report of the State Board of Medical Registration and Examination of Ohio, 1896. Cloth, 180 pages.

The report of the Secretary and an official register of physicians, arranged by counties, occupies the major portion of the book. There is also an index to the official register: 1. Graduates. 2. Legal Practitioners. An alphabetical list of midwives and of physicians holding one year certificates issued on examination is also given; by the appendix this is brought down to March 8, 1897. The statutes of Ohio regulating the practice of medicine and surgery, occupy thirty-two pages, including a list of colleges recognized by the State Board during and prior to 1896.

Transactions of the Indiana State Medical Society, 1897. Cloth, 500 pages. Illustrated. Indianapolis. 1897.

This volume covers the forty-eighth annual session of the Society held in Terre Haute, May 20 and 21, 1897. Besides the "President's Address" and thirty-seven other papers, the book contains reports of the various committees, stenographic report of the transactions, the Constitution and By-Laws, a list of the delegates, a list of the members and officers of county societies and an alphabetical list of members. The work is well edited and on excellent paper.

Proceedings of the Nebraska State Medical Society. Twenty-ninth annual session. 1897. Cloth, 375 pages. Illustrated. Published by the Society.

This volume contains, as the title indicates, full proceedings of the Society; a list of the officers, a list of the members, forty-six papers, minutes of the session, etc. A well arranged index adds much to the usefulness of the volume which is a credit to the Society both in contents and workmanship.

Illustrated Catalogue of Batteries and Electro-therapeutic Appliances. Manufactured by the McIntosh Battery and Optical Company. Chicago.

This edition contains descriptions of many new appliances and is fully up to the standard of its predecessors. The net prices of the articles are substituted in place of gross amounts admitting of misleading discounts.

PUBLIC HEALTH.

Yellow Fever.—An outbreak of yellow fever is officially announced at Ocean Springs, Miss., and one case has appeared at New Orleans, traceable to a sojourn at Ocean Springs. As usual the initial cases were termed cases of dengue, and the suspicions of the public if any existed were allayed, but "yellow jack," like murder, "will out," and the discovery has created something very like a panic in those places where the people were accustomed to go to Oceans Springs, Pass Christian, Biloxi and Pascagoula for the sea bathing, and gulf breezes. The usual talk of shotgun quarantines is heard, and stringent quarantine and inspections by the duly authorized State officers. In the hands of Dr. Saunders, Dr. Oliphant, Dr. Patton, Dr. Haralson, Dr. Eugene Wasdin, M.-H.S., and others the public may be assured that all will be done that can be done to prevent the spread of the disease. That their effort may be crowned with success is the fervent wish of every sanitarian, but the number of cases that is reported, makes it probable that even the best directed efforts will not avail to prevent other cases here and there. Prompt isolation of these cases, which will occur this week if at all, will prevent a further spread. It is too soon just now to say much about the origin of the epidemic, although its source is doubtless easily discoverable and was long ago pointed out.

A Yellow Fever Suspect at Boston.—At midnight, August 31, the steamer *Orion*, Captain Smith, bringing 2,058 bales of wool from the wrecked steamer *Ethel Gonda*, arrived at quarantine and was there detained several hours. One of the divers died at St. Lucia on August 12, after a two weeks illness of what might have been by liberally doubting "Chagres fever," but as during the voyage other suspicious cases were developing one of the party was taken ashore at Galloup's island to be under observation for two or three days. The culture method is to be resorted to for diagnostic corroboration. The effects of the crew however were thoroughly fumigated before the steamer was allowed to come to Boston.

A Quarantine Against Smallpox has been declared against trains from Montreal by the Health Board of Ottawa.

Cholera in Bombay now seems to be replacing the plague, and the city's sanitary condition is still far from perfection.

The Inter-State Conference on Convict Labor will meet during this month at Nashville, Tenn. What is wanted is a system under which all able-bodied convicts will be kept at work and treated humanely. There must be a golden mean between idleness and the chain-gang.

Great Britain in the Van.—A motion is to be made in Parliament, as soon as it reassembles, "that in the opinion of the House of Commons it is desirable that a Department of Public Health be constituted, and that the same be under the charge of a responsible minister having a seat in Parliament."

Health in Michigan.—The August report, as compared to that of July (*vide* JOURNAL, August 28, p. 452), shows consumption was present at 193 places; measles at 52; diphtheria at 39; scarlet fever at 28; whooping cough at 23 and typhoid fever at 56 places. Compared with the August average for eleven years (1886–1896) influenza was more prevalent, and remittent fever, dysentery, cholera infantum, intermittent fever, cholera morbus, consumption and inflammation of the bowels less prevalent.

Yellow Fever at Colon.—A news item in the New York *Tribune* (August 31) is to the effect that the Colombian authorities are striving to suppress the true condition of affairs, and with somewhat of success as the physician in charge is a government employe, Dr. Randall, reports ten cases and seven deaths in the French hospital at Colon, and adds that he knows at least six cases of yellow fever that died there whose names do not appear. He believes that there have been three times as many cases with the same ratio of deaths as stated in his report. Dr. Randall adds that there have been treated at the St. Thomas Hospital, Panama, to the above-mentioned date thirty-six cases with fourteen deaths, and at the French hospital fifty-eight cases with twenty six deaths.

Bubonic Plague Prophylaxis.—Dr. Haffkine (*Crit. Med. Jour.*) utilized the knowledge gained by Koch in his cholera bacillus experiments, namely, that the bodies of Koch's bacilli cultivated on solid media, when inoculated into persons exposed to cholera, produce a reduction of susceptibility and of the absolute mortality from the disease without affecting the case mortality. He therefore combined the bodies of the microbe with the toxins secreted in the surrounding media. The procedure was the killing of the microbes by a temperature of 70 degrees C., and then the use as a prophylactic injection of the nutrient fluid containing the dead microbes, along with the toxins produced and held in solution. From January 10 to May 6, 1897, 11,362 have been inoculated with the fluid with but twelve fatal cases. Of these, three were already sick at the time of inoculation. and three others contracted the disease within twelve hours of inoculation. The question seems to be between mitigation and cure.

Value of Antitetanus Serum as a Preventive.—Nocard reports to the Académie de Médecine of Paris, as the result of thorough investigation, that antitetanus serum is *unfailingly and absolutely effective in preventing tetanus.* He has distributed 7,000 vials since August, 1895 each containing 10 c.c., and he reports the effect on 2,727 animals (2,395 horses, donkeys or or mules; 44 bulls; 82 rams or lambs and 206 hogs. Each received two injections at an interval of ten to twelve days (20 c.c. for larger animals and 6 to 10 c.c. for the smaller). Three hundred animals received the preventive injection immediately after an operation (castration, amputation of the tail, ablation of tumor, operation for cryptorchidia or hernia, etc.), and not a single animal was affected with tetanus. A second group includes 400 animals which were injected with the serum from one to four days after an accident, a fall, bite or kick from another horse, bruise, wound soiled with dirt or manure, etc., none of whom succumbed to tetanus, and only one contracted the disease, a horse injected five days after an injury at the hands of the farrier. The disease was extremely benign in this case and the horse was at work again seven days later. A weak dose of the serum is sufficient to prevent tetanus if injected shortly after the animal has received the dose of toxin inevitably fatal for the control animals. The tests were made in localities noted for the prevalence of the disease, some of the farmers having been compelled to abandon certain operations that enhanced the market value of their stock on account of the number lost by tetanus. His sixty-three correspondents, while testing the serum, observed 259 cases of the disease in their other animals not treated (191 horses, 57 rams and 11 cattle). The *Bulletin*, July 27, contains the tabulated details.

Anthrax in Pennsylvania.—The recent outbreak of anthrax in Pennsylvania may arouse a controversy in which more than one of the National Bureaus may be involved. The Secretary of the Treasury is to report the facts to the Secretary of the Department of Agriculture as soon as he returns to Washington. The exclusion of infected foreign hides is a subject with which the Treasury Department alone has to deal, but the regulations for the disinfection of such hides before shipment to the United States were formulated in the first instance by the Chief of the Bureau of Animal Industry, recommended by the Secretary of Agriculture and adopted by the Treasury Department. The carrying out of these regulations is one of the duties of consular officers of the United States in foreign countries from which hides of neat cattle are exported to the United States. The Pennsylvania case is not a new one, except that it involved the loss of human life, that loss being attributed to the results of tanning infected foreign hides, but the subject is beset by serious difficulties. In the first place, the law itself is defective. It applies only to "neat cattle and the hides of neat cattle," whereas the skins of sheep and goats, and wool and hair also, may be infected with the germs of anthrax and other infectious or contagious diseases. The intent and purpose of the law as expressed in the statute are to prevent "the introduction or spread of contagious or infectious diseases among the cattle of the United States." In the second place, anthrax is a disease which is not uncommon among domestic cattle, the hides of which are offered for sale in the domestic markets. Moreover, according to the best authorities, it is exceedingly doubtful whether by any process of disinfection the vitality of the germs of anthrax can be destroyed. That is the opinion of Dr. Salmon of the Department of Agriculture, who has devoted much study to the subject.

Alien Rule as a Conservator of Races.—An item in an English paper, with the census of Egypt as an inspiration, points out a gain of 42 per cent. in the population during fifteen years, the greater part of which has been gained during the British occupation. By a curious coincidence a French newspaper also comments upon the French-Canadian increase from 70,000 in 1765 to 1,800,000 in 1891, and more than two million at present. At the close of the civil war in the United States an official enumeration of the population of British India, made by the British Government in 1867, put the population of that country at 144,000,000 exclusive of 47,000,000 inhabitants in districts under British jurisdiction but not under direct British control. This was thirty years ago and the population of India at that time was 191,000,000 in all. By the last imperial census made by the British authorities, the population of India was 287,000,000. The credit of the phenomena is cheerfully given to the introduction of superior sanitary regulations and to a government with a more just dispensation of rational laws as well to a greater premium on life-values in general. Dependence or even antagonistic rule does not seem to have been a factor in these conclusions. The French Canadians who have shown, during the past century, so large an increase, are exhibiting in their colonies in New England a like, if not a larger, ratio of increase, the material conditions in the United States being better than they are in Canada. Australia is another English dependency, though it is less dependent than most English colonies, which has shown a remarkable increase in population during the past twenty years, whereas those Danubian States which acquired their independence some years ago have advanced some in population though relatively little when compared with the neighboring States either left under Turkish jurisdiction or put under the rule of Austria. May not clanship with its more agreeable domestic relations, an acceptance, tacit though it be, of the caste system, and the cheerful acceptance of surroundings have more to do with these results than racial pride cares to admit. Still the subject is a most interesting one as proven by the plaudits of the press for the broad English philanthropy exhibited during the plague and famine in India.

Respiratory Manifestations of Plague.—The *Medical Press and Circular* calls attention to the fact that a very material source of error appears to exist in regard to the devastations of the plague, in the fact that some of the death losses have been charged against pneumonia and other respiratory causes. Regarding the death of a prominent English official of Bombay, the *Circular* remarks: "He exhibited none of the ordinary signs of bubonic plague, but a bacteriologic examination proved beyond a doubt that his death was caused by the specific organism of the disorder in question. A similar result was obtained in three other cases where hospital patients were reported to have died from pneumonia. In view of these facts, the mortality returns of all places where plague has been epidemic will have to be read by the statistician in a fresh light. In Bombay, for instance, there has been of late an enormous increase in the official list of deaths published under the head of 'respiratory diseases.' It may fairly be assumed that a proportion of such cases, although diagnosed as pneumonia, fever, or bronchitis, were really due to bubonic plague of an atypical or ambulant form. The danger of non-recognition of so virulent and eminently contagious a disease is sufficiently obvious to require no more than passing mention. The fact of such an occurrence has long been known to medical writers on the subject, but it may be doubted if it has gained anything like wide recognition. The reason for this local manifestation offers a problem of great interest and importance to the scientific [illegible] investig

Mytilotoxin, the Ptomain of the Mussel.—The oyster is not the only shell-fish that is dangerous to man, when obtained for food from localities that are near to sewage outlets. Dr. Ridley Bailey, medical officer of health of Bilston, England, in a recent report, records an instance in which four persons, visitors to Blackpool, were seized with symptoms of ptomain poisoning shortly after consuming raw mussels procured from the vicinity of a sewer outfall, and two of these four persons subsequently developed enteric fever at such a date after the ingestion of the mussels as to render it highly probable that the shell-fish were the means of conveying the disease. These facts were reported to Dr. Jasper Anderson, medical officer of health of Blackpool, who stated that there were at that place in October last no less than six cases of enteric fever which had apparently been caused by the ingestion of raw mussels procured from a bed where sewage contamination was a matter of probability. Dr. Anderson very properly had notices placed on the mussel beds warning the public as to the danger of consuming the fish. Ptomain poisoning as the result of eating mussels dates back, however, considerably earlier than 1883, and it is recorded that in 1827 some thirty persons were attacked with serious symptoms, which in two cases ended fatally, after eating mussels collected from the dock gates at Leith, and animals to which some of the mussels in question were given were similarly affected. Amongst other disasters of a like nature may be mentioned that of Wilhelmshaven, where the mussels which caused the mischief were procured from the bottoms of two vessels in the harbor; and in 1890 there occurred what was known as the "Seapoint calamity," in which a mother and four children died from the effects of eating mussels procured from a locality to which sewage had access. There is still much to be learned in connection with the subject of mussel poisoning, but it is obvious that there are other factors than idiosyncrasy involved. It is generally considered that the poisonous effects are due to what is known as mytilotoxin, a poison produced by the agency of bacteria which have as a rule been conveyed to the mussels through the sewage pollution of the water in which they have grown or been placed; and although there would seem to be certain instances on record in which sewage could hardly have polluted the water, a large number of outbreaks have been caused by mussels taken from places liable to pollution of one kind or another, and there is thus evident need for some control of the mussel industry. The cooking of all mussels intended for human consumption would doubtless do much to remove the risks of contracting enteric fever, but this process would not be equally effective against ptomain poisoning. In this latter connection it may be of practical utility to record that in the Wilhelmshaven outbreak, which was investigated in one or another of its aspects by numerous observers, amongst whom were Virchow and Salkowski, it was discovered by the latter that mytilotoxin became inactive when treated with carbonate of soda, and that mussels boiled for some six minutes in a solution of this salt lost their toxic properties, a fact which appears to afford indication for treatment in cases of poisoning by mussels.

Sewer Air and Sewer Gas.—It has been chiefly in England that the injurious action of sewer gases escaping into houses was insisted upon and typhoid fever was one of the principal diseases attributed to these causes. The reports of Simon on the Sherborne epidemic in 1872 and of Buchanan on the outbreak of typhoid fever at Caius College in 1873 are quoted as representative of the opinion of English experts. In contradistinction to these views, the majority of writers on hygiene in Germany maintain that sewer gases are incapable of disseminating typhoid fever or other infectious diseases; and, in support of these conclusions, allusion is made to the investigations of Flügge, Gärtner, Preusnitz, Rubner and Soyka. As early as 1881 the last named authority demonstrated by statistics at the Vienna meeting of the society that cities provided with sewers were not in any way more liable to the attacks of diseases of this type than those wholly undrained; indeed, he proved the converse of this theory and showed that in a series of towns which had recently been sewered on the modern system the mortality from typhoid fever had diminished and that in those parts of the towns where the sewerage was defective the cases of typhoid fever were more frequent and more severe than in those quarters which were well drained. Many other authorities were cited and figures given to show the condition of drained and undrained towns, among which the facts relating to Dantzig and Munich before and after the introduction of drainage are recorded, also the investigations of Baron into thirty-seven undrained towns and forty-six towns provided with a system of sewers. Passing thence to the discoveries of Pasteur and Koch and their followers it is shown that a correct knowledge has now been gained of actual disease germs and of the best means of withstanding them. It may be pronounced with absolute certainty that any given disease can only occur when the known organism recognized as the active agent of the same has acquired vitality. In the absence of the typhoid bacillus there can be no typhoid fever, and where there is no cholera vibrio there can be no cholera. The gases caused by putrefaction, however poisonous they may be, can not produce diseases of the above kind. The author points out that certain of these pathogenic germs which may enter the sewers mixed with fecal matters and soiled water do not find in them very favorable conditions for their existence, and that for the most part these organisms lose their virulence in sewage water. In order that the sewer-gas theory may be realized it must, however, be assumed that certain of these infectious germs are capable of floating in the air and thus entering dwellings. Nageli has, however, shown that this is not possible and he has proved that these germs can neither ascend into the air nor be given off from moist surfaces; and in the air of sewers, moreover, bacteria have been ascertained to be invariably present in but small numbers; indeed, frequently such air is absolutely free from these organisms. Uffelmann has been at some pains to ascertain the species of bacilli found in sewer gas and a list of these is given. It is stated that it follows from these arguments that there is no proof of there being any connection between sewer gas and the spread of epidemic diseases. On the question of the extent to which, apart from their liability to spread disease, sewer gases may prove injurious to health the author asserts that this depends mainly on the degree of concentration in which certain undoubtedly poisonous gases exist which are found in sewers and other places where putrefying matters are collected and stored. The thorough and effective ventilation of sewers and soil pipes is the best mode of combating this evil. A distinction is drawn between sewer air and sewer gas and it is pointed out that the latter can only form in sewers which contain dead ends and in other places where effective ventilation is wanting. In well-constructed sewers the contents pass away freely and rapidly without undergoing putrefaction and the air in such sewers is in no way unhealthy. The house drains and soil pipes are much more likely to engender evil smelling and injurious gases than are the sewers.—Dr. S. W. Abbott in the *Boston Medical and Surgical Journal*, April 8.

NECROLOGY.

EDWIN M. KITCHEL, M.D., assistant professor of histology and pathology in his Alma Mater, the College of Physicians and Surgeons, New York, died as a result of injuries received by falling from a piazza, in the course of a game of "blindman's buff." This occurred at the summer home of his family at Hulett's Landing, Lake George, on the evening of August 24. The patient was taken to Roosevelt Hospital, New York City, but death from the spinal injury resulted August 26 at 1 A.M. He was the only son of James T. and Irene A. Kitchel of Newark, N. J.

J. D. THOLOZAN, M.D., born in France in 1820, served in the army and as professor at Val de Grace until 1865, when he was sent to Persia in an official capacity and became in time the body physician of the late Shah of Persia, which reponsible position he filled for thirty years, and accomplished much in introducing hygienic and sanitary ideas into the country. He was an *associé national* of the Acad. de Méd. and of the Acad. des Sciences, and also commander of the English order of St. Michael and St. George, which conferred the title of Sir upon him. His best known works were on the "Bubonic Pest," "Cholera," the "Causes of the Decadence of the Mussulman Nations," and "Pulmonary Hemorrhage," with several treatises on quinin, etc., published in Persian.

A. H. Bailey, M.D., Santa Cruz, Cal., August 24.——E. L. Finley, M.D., Streator, Ill., September 1, member Illinois State Medical Society.——George Sproson Jones, M.D., Covington, Ind., August 25, aged 56 years.——F. M. Pearman, M.D., Warsaw, Ind., September 3, aged 61 years.——John A. Richards, M.D., Farmington, Me., August 28, aged 68 years.——Thomas J. Hayes, M.D., Beverly, Mass., August 26, aged 35 years, member of the Massachusetts Medical Society.——J. E. Albee, M.D., Detroit, Mich., September 1.——John M. Swift, M.D., Northville, Mich., August 30, aged 65 years.——William H. Brinley, M.D., Minneapolis, Minn., September 1, graduated from Yale Medical Department, 1881.——George W. Vogler, M.D., Philadelphia, August 26, aged 42 years, at Estes Park, Col.——H. R. O'Connor, M.D., Pittsburg, Pa., August 30, aged 44 years.——Dr. Ballue, of Paris and Arras, drowned from collision of his yacht *Priny* with the Belgian mail steamship, of Dunkirk, aged 40 years.——Benjamin R. Whitaker, M.D., University Pennsylvania, 1866, of Phenixville, Pa., died in Philadelphia, August 18, aged 53 years.——John R. Cabell, M.D., University of Virginia, 1850, was assassinated by a tenant of his farm August 26. He was a resident of Danville, Pittsylvania Co., Va.——Louis Fellows Root, M.D., College of Physicians and Surgeons, New York, 1882, died in Tarrytown, N. Y., September 3, of cardiac disease. He was born in Chatham, N. Y., Feb. 19, 1859.

MISCELLANY.

A Source of Wealth.—Last year California marketed 452,110 gallons of mineral water, valued at $249,580.

Cigarette Smoking in Japan is on the increase. Every month 13,000,000 imported and 52,000,000 native cigarettes are being consumed. Women and children smoke almost as much as men.

Carbohydrates in Leuconuclein.—Bang reports that he has succeeded in splitting a pentose from the nuclein of the leucocytes, leuconuclein, in a suppurated tuberculous pleural effusion.—*Deutsche med. Woch.*, No. 21.

Neuropathic Curvature of the Spine.—A careful study of two cases of curvature of the spine by S. J. Popow, is published in Nos. 14 and 15 of *Wratsch.* By exclusion of other pathologic relations he is forced to the conclusion that each case had a neuropathic basis.—*St. Petersb. Med. Woch.*, July 17.

Dulness on Percussion of the Apices without Pathologic Alterations.—In cases of long illness and repose in bed, the muscles become relaxed and the capacity of the lungs diminished. W. M. Kernig reports thirty five such cases in which, while the lungs were normal, there was dulness on percussion.—*St. P. med. Woch.*, July 17.

The Blood After Resort to Higher Altitudes.—The increase in the number of red corpuscles is more marked and more rapid in consumptives in the early stages than in healthy persons. An altitude of only 236 meters is sufficient to produce the increase. —Meissen and Schröder, *Münch. med. Woch.*, No. 24, in *Wien. klin. Rund.*, July 18.

Electric Conductibility of Animal Fluids.—Prof. A. v. Koranyi has continued his researches on the osmotic force and molecular concentration of animal fluid, which have led him to the discovery that the electric conductibility of the fluids can serve as a measure of the volume of serum and of the blood corpuscles, and thus has a direct diagnostic value. Full details of the investigations are to be published at once in the *Zeitsch. f. klin. Med.*, but the preliminary communication is in the *Cbl. f. Phys.*, July 10.

What Constitutes an Exploratory Operation.—The opening paragraph of an editorial in the *Medical and Surgical Reporter* (August 7) thus defines: "An operation begun for the removal of diseased organs and ending in failure to remove the pathologic conditions found should not under any circumstances be termed an exploratory operation. It should have applied to it the new term 'inoperable,' or should be designated, according to the vernacular, a 'flunk.'"

Absorption of Fats from Enemas.—Deucher has found that fat is absorbed from enemas, but never more than 10 grams at most, even in experiments lasting twenty-four to forty hours. The absorption is favored by administering the fats in the form of an emulsion, adding 6 per thousand salt solution, warming to the temperature of the body, careful cleansing of the intestines previously and long retention.—*Cbl. f. Phys.*, July 10.

Calculus in the Urachus.—The patient complained of pain in the abdomen and retention of urine appearing suddenly after twelve years of turbid, often bloody urine. A tumor was palpated in the median line between the umbilicus and the symphysis. When removed it was found to consist of a large phosphatic stone enclosed in a sac of tissue, communicating with the bladder by an opening as large as a forefinger. The calculus weighed two and three-fourths pounds.—*St. Petersb. Med. Woch.*, from *Wratsch*, No. 1.

Impermeable Gelatin.—According to the *Revue Scientifique* a company has been organized to manufacture waterproof paper for dressings, etc. The paper is dipped in a solution of 1,000 grams gelatin dissolved in four liters of water with 1,000 grams of glycerin. After it has been well soaked in this it is again dipped in a solution of 750 c.c. commercial formol, with distilled water q. s. to make five liters and dried, when it becomes impermeable, resisting even the action of direct steam.—*Nouv. Remèdes*, July 24.

Exteriorization of the Sensibility.—By this term Joire designates the condition he has observed in a few peculiarly susceptible hypnotic subjects in which the skin is anesthetic, but there seems to be a zone surrounding the blindfolded subject at a little distance, in which he feels pricks and pinches of the empty air as if they were made on corresponding portions of his person. A needle inserted noiselessly in a glass of water held between his hands, affects him like a prick, and even a pencil pointed at him he feels as if pressed against normal skin. Some interesting observations are described in the *Nord Méd.*, July 15.

Surgical Intervention in Tuberculous Meningitis.—D. Ssokolow trephined the skull in two cases of tuberculous and one of suppurating meningitis, and although the three patients died soon afterward he considers that the temporary benefit obtained justifies further attempts. He advises trephining the parietal eminence, opening the membrane first. If no fluid appears, the lateral ventricle must be punctured with the trocar. He also suggests that the introduction of air might be beneficial, as in abdominal tuberculosis; lumbar puncture made simultaneously would facilitate the introduction of air.—*St. Petersburg Med. Woch.*, July 17.

The British Association for the Advancement of Science ended its sixty-seventh annual meeting at Toronto, Canada, August 25, with a dinner given to about four hundred guests. The meeting this year was generally regarded a very satisfactory one. There were full programs, able papers, fine weather in an unequivocally clean city, and exceptionally convenient buildings for both the large and the small gatherings. The lovemaking between the two parts of the British Empire, the presence of so many Americans and the remarkable number of garden parties given in honor of the visitors were other features. Some of the over-sensitive talked about the scant mention of the Americans, without regard to the dictum that there is "no courtesy in science," and turned idly away after having seen Lord Lister. The majority, however, seemed pleased as well as edified by their share of paleontology, botany, anthropology and geology, while medicine contented itself as usual with a "Vanity Fair" exhibition of its progress.

Correction.—Through error in copy the "Response to the Address of Welcome to Delegates from the American Pharmaceutical Association," was credited to F. W. Stewart, instead of F. E. Stewart (*Vide* JOURNAL, August 21, p. 355).

Turnip Plates for Gastro-enterostomies.—R. v. Baracz contributes a review of the various methods of performing this operation, to the *Wiener Klinische Woch.*, of July 22, expressing his preference for Senn's plate method as the best in all respects; as shown also by the statistics when compared. He, however, advocates making the plates of turnip, and describes an observation that confirms his views, supplementing a previous observation of his own, one by Heigl, and two by Butz. The turnip is absorbed in a few days. He considers gastro-enterostomia antecolica simpler and easier, and advises having on hand a couple of pairs of plates, made fresh, to allow a choice when the size of the intestine is disclosed.

Lauwers' Method of Abdominal Hysterectomy with Buried Pedicle.—He performs supravaginal amputation of the uterus according to Hofmeier, Fritsch, Chrobak and others, but modifies it by detaching a large flap of the peritoneum from the anterior surface of the uterus down to the collum uteri, which exposes the uterine arteries and permits their being ligated separately. After amputation down to the collum the mucosa and musculature of the cervix are cut as necessary and sutured. The anterior peritoneal flap is then drawn over the sutured uterine stump and sutured to the peritoneum behind it. This cover over the stump prevents the slightest infection by way of the vagina. Fifty operations; mortality 4 per cent.—*Cbl. f. Chir.* July 24.

Rare Case of Hemorrhagic Bacterial Septicopyemia.—A strong, perfectly healthy young man was taken suddenly with chills, pains in the limbs and with a few ecchymoses on the lower extremities, but no other symptoms, no ulcerations nor sensitive areas. The third day delirium set in; the whole body became covered with the cutaneous hemorrhages, with albumin, red corpuscles and hyalin and granulated casts in the urine; the lungs and blood remained normal. Temperature rose to 40.5 degrees C. Death occurred the sixth day. The necropsy disclosed pus foci in the brain, eye, retropharyngeal space, suprarenals and articulations, although they had not been swollen *intra vitam;* also hemorrhages into the various organs, parenchymatous nephritis and fresh verrucous endocarditis. The presence of staphylococcus pyogenes albus in the blood was established.—J. Gwosdinski, in *Russkij Archiw* No. 3, in *St. Petersb. med. Woch.*

The Lloyd Jones Theory of Chlorosis.—A waif from the *British Medical Journal*, July 25, which in a spirit of space economy we are obliged to condense, sets forth the following: Roy's invention for weighing a drop of blood is the inspiration of the investigation, and the blood examination of 1,400 healthy persons constitutes the basis of what may even yet prove an hypothesis. The weight of blood varies with the quantity of hemoglobin and less closely with the number of cells. "Nothing," says Lloyd Jones, "is more characteristic of chlorotic blood than extreme diminution of red blood corpuscles together with an equally marked reduction in the amount of hemoglobin." This result is obtained not by counting the cells but by measuring their volume centrifugally. Chlorosis has some seeming connection with child bearing, for lighter blood indicates greater fertility and dark complexioned people are less prolific. "With these views," says the *British Medical Journal*, "it is natural that he (Lloyd Jones) should hope to explain chlorosis by some auto-intoxication from the generative organs. The ovaries have failed him hitherto and he is now examining the uterus. He has no difficulty in showing that the stomach and intestines have not yet been proven guilty. Whether he will have more success with the organ now accused remains to be seen."

Rapid Technique for the Preparation of Eyes, etc.—The enucleated eye or other small organ is placed immediately in 10 per cent. formol, from which it is transferred after twenty-four hours to the following solution: Formol, 20; sodium phosphate, 40; glycerin, 300; aq. dest., 1200. This solution is renewed every day for eight to ten days. This process preserves the coloring of the eye and its normal relations. A glass jar is then filled with melted jelly and the eye placed in it, the concavity down. When the interstices are filled the eye is turned over, care being taken not to include bubbles of air. When the jelly is set, the jar is closed with a sheet of glass and fastened with Canada balsam. The jelly is made of 8 parts of pure gelatin to 8 parts each of glycerin and water. The gelatin is dissolved in the water at a moderate temperature, the white of an egg is added and the whole boiled, then filtered through flannel and the glycerin and an antiseptic added (thymol, phenic acid, formol), which preserves the jelly without injury to the piece.—*Jour. de Méd. de Paris*, July 25.

Surgeon General J. Rufus Tryon, U. S. N., on September 7, completed the term of four years for which he was appointed, but does not reach the retiring age until Sept. 24, 1899. The Secretary of the Navy is giving the application of the Surgeon-General for reappointment his strong support so as to fulfil the unwritten law to permit him to retire with the rank and pay of the highest grade filled by him. In this respect his case is similar to that of his predecessor, Surgeon-General J. Mills Browne, and other heads of staff corps at the present time. Surgeon-General Tryon is a native of New York, a graduate of Union College and the medical department of the University of Pennsylvania, class of 1861. He served with distinction during the War of the Rebellion, and in the line of duty has visited nearly every port of the habitable globe. In 1874 he volunteered for service during the yellow fever epidemic—an act for which he was specially commended by his superior officers. His administration of the medical department of the Navy during his term of office has been conspicuous for the many changes and improvements instituted, all tending to the advancement of the Medical Corps and to the care and comfort of the sick and wounded in the Navy.

Liability for Autopsy on Dead Body of Child.—The question was raised on demurrer, in the case of Burney v. Chidren's Hospital in Boston, whether the father of a child, who is its natural guardian, and who has intrusted the child to a hospital for treatment, can maintain an action against the hospital for an autopsy performed on the dead body of his child without his consent. The sole contention of the counsel for the defendant hospital was that no such action could be maintained, because there is no right of property in a dead body. But the supreme judicial court of Massachusetts says, June 16, 1897, that the father, as the natural guardian of the child, was entitled to the possession of its body for burial. Being entitled to the possession of the body for the purposes of burial, it then asks, is not his right against one who unlawfully interferes with it, and mutilates it, as great as it would be if the body was buried in his lot and was thence unlawfully removed? That an action may be maintained in the latter case there are decisions showing; and, although it is a new question in Massachusetts, the court holds that an action may be maintained in the former case. This is in line with several well-considered decisions in other States. But it was not argued by its counsel whether the nature of the defendant hospital was such that an action against it could not be maintained for the alleged illegal acts of its officers and servants, and the court refrains from expressing an opinion upon it. Nor did it feel disposed to inquire under what circumstances an autopsy is justifiable—leaving both questions until the facts should be before it, after trial.

Resection of the Cervical Sympathetic vs. Thyroidectomy in Basedow's Disease.—Jaboulay reports three new cases in which he has resected the cervical sympathetic, raising the total to fourteen cases on record (the first in 1896), all of which have shown constant improvement. Péan, on the other hand, rejects this operation as transient in its effects, as he performed it in one case three years ago, principally to cure a concomitant epilepsy. There was at first marked improvement of both troubles, but the success was not permanent and he never tried it again. He advocates thyroidectomy for Basedow's disease, stating "that it should only be performed after medical treatment has failed and before the disease has exhausted the strength to the point of compromising existence. The operation is easy when the goiter is small, not inflamed and readily enucleated: a few minutes are all that is necessary to remove the tumor through a small median, vertical incision without any necessity of ligating the vessels if his hemostatic forceps are used, which serve also for retraction. Even in the most serious cases the operation is not difficult, but the tumor should be removed by morcellement after compressing the vessels. Consecutive myxedema is rare and transient." If the patient is troubled by hypersecretion of the laryngeal and tracheal liquids he suspends the operation, raises him to a sitting posture and removes the mucus with a mounted sponge. "Section of the cervical sympathetic and exothyropexy have not yet recorded a sufficient number of cures to be profitably opposed to thyroidectomy."—*Bulletin de l'Académie de Méd.*, August 3.

Solidity in Radical Cure of Hernia.—Lucas-Championnière has performed this operation 650 times in the last sixteen years, and his success in securing such solidity that the patient is less exposed to hernia afterward than one who has never been ruptured, leads him to raise his voice in protest against any method of cure that does not absolutely remove the serous funnel or close up the inguinal ring as inevitably superficial and imperfect, referring especially to the Lannelongue chlorid of zinc cure. He emphasized the necessity of freely opening up the hernia, excising all the omentum accessible, destroying the sac and its infundibulum and restoring and strengthening the walls by crossing the flaps, closing with drainage. With this method he has only had twenty relapses in all and five deaths (two avoidable). One relapse was a butcher who lifted a whole side of beef on the end of a pole: another relapsed during an attack of whooping cough. He slyly adds that there is not much chance of any relapse having occurred without his knowledge, as patients and colleagues are not diffident about reporting them. He has had one relapse in his last 200 cases. Rapid obesity is the principal cause of relapses, as he has already proclaimed (*vide* JOURNAL, vol. 28, p. 556).—*Bull. de l'Acad. de Méd.*, August 3.

Liability for Bodily Injury Caused by Fright.—Whether, in an action to recover damages for an injury sustained through the negligence of another, there can be a recovery for a bodily injury caused by mere fright and mental disturbance, was a question never decided in the State of Massachusetts, until the supreme judicial court handed down its decision, May 19, 1897, in the case of Spade v. Lynn & Boston Railroad Company. The court holds that there can not be. It says that it remains satisfied with the rule that there can be no recovery for fright, terror, alarm, anxiety or distress of mind, if these are unaccompanied by some physical injury; and, if this rule is to stand, it thinks it should also be held that there can be no recovery for such physical injuries as may be caused solely by such mental disturbance, where there is no injury to the person from without. The logical vindication of this rule it declares is that it is unreasonable to hold persons who are merely negligent bound to anticipate and guard against fright and the consequence of fright, and that this would open a wide door for unjust claims, which could not successfully be met. But the court takes pains to add that this decision does not reach those classes of actions where an intention to cause mental distress or to hurt the feelings is shown, or is reasonably to be inferred, as, for example, in cases of seduction, slander, malicious prosecution or arrest and some others. Nor does it include cases of acts done with gross carelessness or recklessness, showing utter indifference to such consequences, when they must have been in the actor's mind.

Paget's Disease of the Skin.—Dr. Rolleston, before the London Pathological Society, brought up the subject of dermatitis maligna, or Paget's disease. Two cases were discussed, in both of which carcinoma had resulted. The first case was that of a man aged 60 years, who had the glazed, raw condition of the skin above the pubes characteristic of the disease for eight years; two years ago nodules of carcinoma developed. The whole affected area was removed and the man recovered. A somewhat similar case, in which the scrotum and penis were affected, had been described by Dr. Radcliffe Crocker. The carcinoma probably developed from the sebaceous glands and not from the superficial layers of the skin. The sweats glands were dilated, but did not, as in Dr. Crocker's case, appear to be undergoing carcinomatous change. The growth was a spheroidal-celled carcinoma. The second case was that of a woman aged 45 years. The skin affection began eight years ago on the sinus of a mammary abscess and had spread most extensively. A year ago carcinoma developed. The whole affected area, together with glands from the axilla, was successfully removed. Microscopically the carcinoma appeared to be squamous-celled, showing a transition to a spheroidal celled type, but no keratinization had taken place. The modification was probably due to the extensive inflammatory changes, which were also thought to be responsible for the extensive vacuolation seen in the epithelial cells. The carcinomatous growth had certainly not arisen in the mammary glands or in the ducts, as is often the case. It was suggested that Sir James Paget's name would best be honored by associating it with the actual morbid lesion, a long-standing dermatitis of the nipple which he originally described, and not with analogous lesions.—London *Lancet*.

American Women Students at Zurich University.—A society has been formed at Zurich by the American women who are studying for a doctorate at that place, and a circular has been issued by it conveying information to others who are looking forward to an educative tour in Europe. It is quoted in the *Consular Reports*, and a part of that quotation is given below: The length of time required for preparation is usually three to four years, except in the case of medicine, when five and a half years of very severe labor are necessary. A diploma from an American college is accepted in lieu of entrance examination. Certificates of successful teaching may also be accepted, but should be submitted in advance, as the decision appears to be made upon the merits of each case. In addition, a certificate of good character is necessary, and for an American, a passport. In the medical school, the entire course is laid down: elsewhere, no course is formulated, but each student is required to choose one major (Hauptfach) and two or three minors (Nebenfaecher). Work is carried on almost entirely by lectures and laboratory work, with occasional quizzes. The fees in Zurich are small. For a course of lectures coming once a week for a semester, the usual charge is 5 francs: for one coming twice a week, 10 francs, and so on. Seminars and quizzes are free. Even when a good deal of laboratory work is done, fees for the entire year rarely amount to more than $60 to $75. There is no university library. It is etiquette in Zurich for a student who is intending to take work with a given professor to call on him in advance at his house, preferably between 11 and 12 o'clock, to anno[illegible] in[illegible] and, nominally, ask his advice. It is im[illegible] that no woman should come to Zurich with the immediate intention of university study, unless she has not only a reading but a speaking knowledge of German. Zurich is not the place to acquire this knowledge; the dialect which one hears almost everywhere in place of German and the number of foreigners of various nationalities in the town make it unsatisfactory for the language student. The university recognizes two classes of workers—the matriculated students and the hearers. The hearers are received without test of fitness, but are admitted to examination and receive certificates of having attended given courses of lectures only through the courtesy of the lecturers. The matriculated students have a few privileges not granted to hearers, and usually, though not necessarily, take an examination. The latter consist of the teacher, the doctor and the State examination. Of these, the second is the only one likely to be of especial interest to students who intend to return to America.

Washington.

COLUMBIA HOSPITAL.—The annual report of the Columbia Hospital for the year ended June 30, 1897, shows 55 patients in the hospital, July 1, 1896; admitted during the year 624; discharged or left during the year, 578; died, 36; remaining under treatment July 1, 1897, 47; death rate per cent. during year, 5.27; prescriptions compounded, 8,644; daily average of patients, 47.84; daily average of babies, 10.93.

PHYSICIANS TO THE POOR APPOINTED.—Drs. John W. Shaw and Rosier Middleton have been appointed alternate physicians to the poor.

DR. LINCOLN'S ILLNESS.—Dr. Lincoln, who has been seriously ill for some days past, is now convalescing and expects to be able to resume his practice very shortly.

FINED FOR ILLEGAL PRACTICE.—A colored laborer in one of the city drug stores has been engaged in practicing medicine illegally and was fined $50 in the police court.

ACCIDENT COMPANY SUED.—Suit has been entered in the district court against the Massachusetts Mutual Accident Association and the National Accident Society of New York, by the widow of the late Dr. Benjamin B. Adams to recover $5,000 from each of the defendant companies, on account of policies issued by them to her husband. The plaintiff claims that the companies have failed to pay the amount stated, though she satisfactorily complied with the rules of the company governing such cases.

Colleges.

THE MAINE MEDICAL SCHOOL may remove from Brunswick to Portland, in which latter city the sum of $100,000 has been pledged for the erection of suitable buildings. An attempt to realize $20,000 of the fund left by the late Joseph Walker to promote education may be frustrated inasmuch as the city of Portland has filed an application with the trustees of the fund for $26,000 wherewith to begin a manual training school.

Societies.

THE CANADIAN MEDICAL ASSOCIATION held its thirtieth annual meeting in Montreal, Canada, August 30, a day previous to the meeting of the British Medical Association. In compliment to the latter Association, some of whose members were present, words of greeting were expressed. After the necessary executive business, the following officers were elected: President, Dr. J. M. Beausoleil, Quebec; vice-presidents, Drs. A. M. McPhedraw, Toronto, C. S. Parke, Quebec, R. A. McKean, Glace Bay, T. R. Tuck, St. John, R. McNeil, Stanley Bridge, J. R. Jones, Winnipeg, F. C. McWheen, Lethbridge, and J. Tunstall, Vancouver; general secretary, Dr. F. N. G. Starr, Toronto; Treasurer, Dr. H. B. Small, Ottawa.

THE PUBLIC SERVICE.

Army Changes. Official List of Changes in the Stations and duties of officers serving in the Medical Department, U. S. Army, from August 21 to 27, 1897.

Capt. W. F. Carter, Asst. Surgeon (attending surgeon, Baltimore, Md.), is hereby granted leave of absence for one month, to take effect about Sept. 1, 1897.

Major Peter J. A. Cleary, Surgeon (chief surgeon, Dept. of Texas, San Antonio (Texas), is granted leave of absence for three months, with permission to go beyond sea.

CHANGE OF ADDRESS.

Behrens, B. H., from Minneapolis to Benson, Minn.

Bates, J. W. P., from 1020 E. Baltimore St. to 1830 Madison Av., Baltimore, Md.

Culbertson, Scott, from Moorefield to Vevay, Ind.

Cook, J. E., from 258 Pearl St. to 514 New England Bldg, Cleveland, Ohio.

Collins, K. R., from Philadelphia, Pa., to Alexandria, Ind.

Caldwell, C. E., from 447 Kimper Lane to 1110 Cross Lane, Walnut Hills, Cincinnati, Ohio.

Carpenter, Julia W., from Bay View, Mich., to 908 E. McMillan St., Cincinnati, Ohio.

Gould, J. B., from Minneapolis to Little Falls, Minn.

Guerard, A R., from 162 E. 114th St. to 2148 7th Av., N. E. cor. 127th St., New York, N. Y.

Gallant, A. Ernest, from 10 W. 36th St. to 60 W. 56th St., New York, N. Y.

Hardman, R. H., from Washington, D. C., to Converse, Ind.

Hengst, D. A., from 515 Penn Av. to 1005 Park Bldg. Pittsburg, Pa.

Koch, I. M., from 706 N. 20th St. to 200 S. 12th St., Philadelphia, Pa.

Lunde, C. A., from Chicago to 252 Woodward Av., Detroit, Mich.

McCurdy, S. L, from 515 Penn Av. to 1023 Park Bldg. Pittsburg, Pa.

Prentiss, D. Webster, from Haven, Me., to Washington, D. C.

Vol. XXIX. CHICAGO, ILL., SEPTEMBER 18, 1897. No. 12.

ADDRESS.

CHAIRMAN'S ADDRESS.

Delivered in the Section on Surgery and Anatomy, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY REGINALD H. SAYRE, M.D.
NEW YORK, N.Y.

When I returned home after the meeting in Atlanta last year, I was most pleasantly surprised to learn from the papers that I had been selected to preside over this Section. I wish to thank you most heartily for the great honor which you have done me in making me Chairman, and especially so for having placed me in this position at this meeting, the most important one which has ever been held by the American Medical Association, celebrating, as it does, its fiftieth anniversary.

The number of papers which have been offered for the consideration of the Section has been so large that I have obliged, much against my will, to decline a great many as all the available time at our disposal had already been fully occupied by papers which had been presented at an earlier date. But I trust the authors will realize that, as our time is limited and as it is impossible to do more than a certain amount in this space, my action was the result of necessity. In my own opinion, it is a mistake to have so large a number of papers as to render it impossible to grant full discussion to those of marked interest, and I think that much more benefit is had from these meetings, if we confine our attention to a smaller number of carefully prepared and thoroughly scientific papers, which enter exhaustively into the consideration of a topic, and have the same discussed by men of experience, rather than to consume our time with the consideration of so large a number of hastily written, incomplete articles, that no opportunity is left for discussion. Oftentimes, the discussion is of as much value as the paper itself, especially so if the author has taken the precaution to send an abstract of his views to various men of experience, in order that they may prepare themselves in advance on the different points which will be brought up, as it frequently happens that time is required to thoughtfully consider new propositions before they can be discussed with intelligence.

From personal experience as Secretary in this Section for two years, in addition to that which I have derived as Chairman this year, I am convinced that we can find a more intelligent way of preparing our program than that at present in force.

That part of the By-Laws relating to papers is: "It shall be the duty of every member, who proposes to read a paper or report to any of the Sections to forward the paper or a title indicative of its contents and its length, to the Secretary of the Section at least one month before the annual meeting at which the paper is to be read. It shall be the duty of the Chairman and the Secretary of each Section to communicate the same information to the Chairman of the Committee of Arrangements concerning such papers and reports as may come into their possession or knowledge for their respective Sections the same length of time before the annual meeting. No paper shall occupy more than twenty minutes. Such papers shall be referred to a subcommittee for their examination, who shall be allowed thirty days for such examination, at the end of which time they shall forward the paper to the Board of Trustees with such recommendation as they may deem proper. . . Every paper shall be the exclusive property of the Association, and be published for its exclusive benefit."

This section should be modified to require the title of the paper to be sent to the Secretary one month in advance and a copy of the paper two weeks in advance of the meeting.

The present method leaves the Chairman largely in the dark as to the amount of work which may be brought before the Section, for unless the copies of the papers to be read before the Section are in the hands of the Secretary at the commencement of the session, it often happens that the gentlemen who have promised papers fail to appear, and the regularity of the proceedings is very seriously embarrassed. The audience also is put to much inconvenience, for the members of the Association, in order to make the best possible disposition of their time, may linger in some other Section to listen to a paper which interests them, coming to this Section at a time when, judging from the program, they might reasonably expect a certain paper to be reached, only to find that it has already been finished in consequence of the absence of a number of other speakers who should according to the program have preceded the paper in question.

It seems to the Chair that the position taken this morning by our President was without question the correct one, that the county societies should be the place for maiden efforts, that those who were thought worthy of places as delegates to the State societies could there present their more mature ideas, while the time of the Sections of the National Association should not be occupied, except by papers of exceptional worth. Papers of this character are not prepared over night and those who desire to appear before this National body should be made to understand that if their papers are not of sufficient importance to justify them in preparing them two weeks in advance of the time of meeting, it is not likely that they will be of sufficient interest to the Section to justify their occupying space on the program.

Another point to which I would like to call your attention is that Article of the By-Laws which states that all papers read before the Sections are the exclusive property of the Association and to be published for its benefit. The ASSOCIATION resolved some seventeen years ago to cease publishing its Transactions in book form and to issue a weekly journal which should contain all the papers read before the ASSOCIATION and its Sections. If we do not support the JOURNAL how can we expect it to succeed. and unless it has exclusive control of the papers presented before the Sections, it is at once deprived of a most vital source of strength and, in consequence, instead of being the most potent factor in making the ASSOCIATION a power in the land, it is handicapped in its competition with other journals by the very men who should be most interested in its support and who should realize that in advancing its interests they are advancing their own, even if they are unwilling to assist from any less selfish motives.

The last few years have witnessed many notable advances in surgery and perhaps the most striking departure from the older methods is the effort to substitute prevention for cure, and following in the steps of Jenner to endeavor by means of the injection of various immunizing agents not only to arrest the ravages of septicemia, erysipelas, tetanus and surgical infectious diseases in general but even to prevent their occurrence by prophylactic injections.

The various reports on this subject are somewhat at variance and the personal equation of the observer must be taken into account. Yet it seems clear that while the successful cases reported are but few, and in some of them doubtless the favorable termination is not to be attributed to the means employed, still certain results have been accomplished and the field of the surgeon seems to be widening day by day and his ability to cope with deadly forms of disease in future will probably be enormously increased through the revival of interest in preventive surgery.

Under the head of preventive surgery come also the new antiseptics which have been brought into use, of which I will mention but a few; loretin, a dusting powder which is free from odor and has proved itself of great use; the oxycyanid of mercury, whose great advantage over the bichlorid of mercury is its noncorrosive action on instruments; calcium permanganate, which is said to be more powerful than the potassium salt, and the formalin-gelatin treatment of Schleich, which promises much in the treatment of infected wounds. This same observer has presented us with eucain, a substitute for cocain as a local anesthetic, which is safer in its effects and produces anesthesia of a more lasting nature.

In conservative surgery we have another instance of the ingenuity of McBurney, who in a case of sarcoma of the radius, instead of amputating the elbow, removed the sarcomotous radius, did a circular amputation in the middle of the forearm and sewed the biceps tendon to the base of the coronoid process of the ulnar thus giving the patient a stump over which he had voluntary control.

Our English brethren have been busy in abdominal surgery and Golding Bird and Harrison Cripps have both suggested plans for avoiding leaking after gastrostomy. Bird makes a small hole in the stomach and, dilating it with a pair of dressing forceps, inserts a rubber tube, claiming that the subsequent contraction of the stomach wall upon the tube prevents the troublesome leaking which so often follows when the opening in the stomach is made larger than the tube and afterward sewed up. Cripps plugs the hole in the stomach or intestines by a piece of rubber tissue as thick as a shilling and a good deal larger than the opening. This he inserts by means of a pair of dressing forceps, having rolled it up After it is inserted the forceps are removed, the rubber disk resumes its normal shape and is pulled tight against the opening by a thread which passes through its center and is fastened to a pin wrapped in gauze and then tied.

In this country Weir and Foote have successfully operated on a round ulcer of the stomach, showing the wisdom of interfering before it is too late for the surgeon to be of use.

The interior of the bowel has also received attention and Stephan has established an artificial anus in a case of obstinate dysentery which had resisted medication, and applied local treatment to the diseased area through this opening, subsequently closing the wound when the dysentery had been cured.

Whenever any operation or invention is good it invites criticism and is modified in various ways to meet the views of the critics. The Murphy button is no exception to this rule, and no less than three different buttons or bobbins of decalcified bone have been recently devised to take its place. The suggestions coming from Chaput, Hayes of Dublin and Jackson Clark of London.

The treatment of diseases of the intestines brings to mind the subject of hernia, and it has always seemed strange to me that we should couple the operation for curing hernia by the reconstruction of the inguinal canal with the name of a foreigner instead of with that of Marcy, who practiced and taught this operation for years without having it generally adopted until it had made a trip across the ocean and returned with a foreign endorsement. I trust that some time in the future the surgeons of this country will give our former President the credit which he deserves.

The urinary tract has also given us examples of progressive surgery, Fenwick having successfully transplanted part of a sheep's urethra to close a defect in man, while the ureters have been the site of many successful surgical procedures both at home and abroad, the chief work of this country having been done by Kelly, Roberts and Van Hook. The kidney itself is now often spared when a few years ago it would have been removed, and in place of extirpation many cases, when a large part of the kidney is healthy, are now treated by the removal of such parts as are diseased. In hydronephrosis, Fenger has been successful in the removal of valve-like formations from the pelvis of the kidney, which prevented the free egress of urine.

Brain surgery still continues to be most daring, and although the results of some of the operations speak more for the thoroughness of technique which renders them possible than for diagnostic skill and reasoning powers of the operator, some wonderful results have been achieved, as in the case of removal of cerebellar tumor from a child 4 years of age, reported by Parkin to the Clinical Society of London.

In the surgery of the vascular system distinct advances have been made. The heart itself has for the second time been sutured successfully but a few months ago as reported by Rehn of Frankfurt, Germany, while the experiments of Murphy have shown that veins and arteries can not only be sutured with success when torn, as had been done in previous years, but that injured portions can be resected and the continuity of the vessel restored by end to end anastomosis with invagination. He has also successfully carried out the same operation in man, though perhaps our scientific brethren on the other side of the water might object to accepting the later cases as the patency of the vessels has not yet been demonstrated on the postmortem table.

The antivivisectionists also might object to the series of experiments which lead up to this successful operation as they have to those of the various workers whose experimental researches have done so much to make clear the hidden mysteries of disease during the past decade, and I feel that a word of warning may not be out of place here to all of you who, relying on the intelligence of our legislative bodies and their certainty of doing the right thing at the right time, believe that the bill now pending before Congress to limit the practice of vivisection will not pass. Unless the medical profession exercises the same assiduity in opposing it that the advocates of the bill show in pushing their scheme both before Congress and elsewhere the bill is very certain to become a law and the entering wedge for acts preventing animal experimentation altogether.

Perhaps the most striking advance that has been made in surgery during the past year has been the discovery of the X rays. It is not my intention to enter elaborately into a discussion of the phenomena which were first described by Professor Roentgen of Wurzburg, in the beginning of the past year, but to deal more especially with their practical application in the field of surgery.

One of the first things that was done, simultaneously, by a number of observers in different parts of the world, was to manufacture apparatus by which the effect of these rays could be seen by the naked eye, in the shape of an opaque box fitted closely to the face, having the surface opposite the eyes coated with a flourescent substance, so that when this surface was turned toward the source of the X rays it became luminous and the shadows of the hand or any other substance could be readily observed. Barium platinocyanid, which Roentgen employed, being very expensive, various other substances were investigated, Mr. Edison having been especially active in this direction, and tungstate of calcium has been found extremely well adapted for the purpose, becoming very luminous and being comparatively cheap. The fact that these rays were capable of affecting the ordinary photographic plate has led to most sudden and widespread interest in this extraordinary phenomenon, and much work has been done in turning these scientific truths to practical account. Skiagraphs are taken with the tube distant about eighteen inches from the patient, as a rule. In some instances the patient lies on the plate, which is covered only by a paper envelope, to preserve it from becoming fogged by the daylight. In other cases a fluorescent screen of paper covered with tungstate of calcium is placed next to the film, the object of the screen being to shorten the time of exposure; but I do not think that the pictures so taken are as clear in outline as those taken without the screen. Both of these methods of observing the interior of the body are of use to the surgeon and have their separate uses.[1]

It was evident from the first that this new discovery opened a wide field in surgical diagnosis, and it has seemed to me that it might be of interest to you to dwell upon some of the conditions in which I have found it of benefit. You all have heard of the numerous instances in which needles have been located, which were otherwise inaccessible, and have heard of the case where an enormous number of bird shot were located in the hand, some in the bones, some in the soft parts, and successfully removed. Another extremely curious fact is that glass is much more opaque to the rays than are many metals, and, in consequence, that pieces of glass, which are often very hard to find when imbedded in human tissues, can be located with ease by this method.

The most obvious use to which this new discovery can be placed is in the location of uncertain fractures and in the differential diagnosis between fracture and dislocation in the neighborhood of a joint. After the fracture has been set and the dislocation reduced it is possible by means of the X-ray to determine whether the dislocation has been satisfactorily reduced, and if the broken fragments are in correct apposition; all this being accomplished while the injured member is in its plaster-of-Paris dressing, so that instead of waiting a number of weeks and removing the dressing to find that the fragments are incorrectly placed, this fact can be ascertained at once and the mistake remedied. In locating foreign bodies that have been swallowed the X-rays have rendered good service. The patient's sensations not always being a reliable guide as to the exact location, while the skiagraph tells us exactly where to operate.

In operations on congenital dislocation of the hip it is feasible, first of all, to take a skiagraph or shadow picture of the pelvis, showing the acetabulum and the displacement of the femur, and later on to take a similar picture showing whether or not we have been successful in replacing the head of the femur in the acetabulum.

In cases of old sequestra in the neighborhood of a joint, it is possible to locate these sequestra, and I believe that it is possible to locate in this manner abscesses occurring in bone, although I have not had a case on which this experiment could be tried.

The localization of foci of disease in the neighborhood of tubercular joints, before the joint itself has become involved, is a matter of much importance and may at times point out to the surgeon the mode by which such a focus may be successfully removed before the disease has invaded the joint.

Another point upon which it has bearing is the differential diagnosis between fibrous and bony ankylosis. In skiagraphs of the normal joint there is apparently a distinct interval between the ends of the bones comprising a joint, which is due to the fact that the cartilage covering the ends of the bones is so very much more translucent than the bone itself that it does not cast a shadow, whereas, in a joint where the cartilage has been absorbed and the bony surfaces themselves brought in contact, this apparent gap does not exist. In studying these pictures more can usually be seen on the negative than in the print, although this is not invariably the case, and a certain amount of practice is likewise necessary in order to permit one to correctly interpret what he sees. I remember being greatly deceived in the first picture which I saw of a child's ankle. I had not seen the child but was told it had been the subject or a railroad accident, and I at once imagined that the fissures which I saw in the skiagraph in the neighborhood of of the ankle-joint were either fractures or epiphysial separations, but on examining the picture of the other leg I found exactly the same gaps in the bone and at once saw that what I had taken for fractures were simply the epiphysial cartilages, which had not yet become ossified, on account of the youth of the subject, and in consequence failed to cast a shadow.

---

[1] Since this address was written it has been suggested to the author by Dr. H. W. Frauenthal that a small fluoroscope fitted to one eye could be used in certain operations, enabling the operator to see with one eye the outer field of operation and with the other the relation of the deeper structures, after the manner of using the camera lucida in drawing microscopic fields. Practical experience with the method has shown it to be difficult to acquire the necessary dexterity of the ocular muscles, but it is believed to be a useful suggestion.

In children this same phenomenon is noticed in the acetabulum and about all joints, where the epiphysis appears as a small button of bone quite distinct from the shaft, and not touching the button of bone which forms the epiphysis composing the other side of the joint. If, however, the exposure be nicely timed the outline of the entire end of the bone can be made out, its shadow being much less dense than that of the ossified center. This same fact makes the skiagraphs of clubfeet of very little importance in children, because the bones are so largely cartilaginous that their relations to one another are rendered very indistinct and only the central parts can be discerned, large gaps apparenrly existing between all the bones of the foot.

It affords us, however, a very striking proof of a fact that all of us must realize as soon as our attention is called to it, that the feet of children are extremely cartilaginous, and that the bones are susceptible, in consequence, of very large alterations in shape, provided they are properly manipulated; and a practical deduction which may be drawn from this is the folly of removing such cartilaginous bones in young children, instead of submitting them to properly directed force, in order that their shape may be so modifed as to correct existing deformities. In cases of web-fingers and supernumerary toes, great use has been made of this discovery in planning operations, as the outward appearance of the hand does not always give a correct idea of the internal relations of the bones.

Calculi in the kidney, ureter or bladder can be detected by this means—the uric acid and oxalate of lime being most easily seen. Gallstones cast too faint a shadow to be found with certainty.

It seems to me that it may be possible, with a better practical understanding of the application of the principles in making these pictures, that good skiagraphs may be obtained of tumors and much light thrown upon abnormal conditions within the thorax and pelvis. I have, as yet, seen no good picture which confirms this view, but the more I have seen of the practical workings of X-ray photography the more I have realized the very delicate adjustment which is necessary to attain certain results.

It must not be supposed that all that is necessary to obtain practical results is the purchase of an induction coil, a battery and a few Crookes' tubes. Practical experience is needed to show the amount of current to be used, the rapidity of interruption, the proper length of a spark, the amount of exposure, and a great many tiresome failures will be necessary before good work can be achieved. The exposure which gives the best definition for bones is altogether too long to give definition for soft parts, and the operator must know in advance what he is trying to show in order to be able to regulate with exactness the conditions to produce a proper result. Again, it is necessary to familiarize yourself very thoroughly with the skiagraph under consideration, and each time that you study it new features will impress themselves on your mind. It often happens that when you return to an old skiagraph after an interval of a few days you will discover various points of interest in it which you failed to detect at the time of your previous examination. The shadows which are cast by various parts of the body are not very well known to us. It is a matter which has been investigated, very superficially, and it will require a large number of observations before we are able to put the proper interpretation upon the pictures that we see. We have to bear in mind that the nearer the plate is to the object which casts its shadow upon it the more clearly defined will be the outline. In many instances some parts of the body which are photographed are much more dense than others and the amount of exposure which is necessary to give the best results in certain places will be too long or too short to give the best results in others, and, in consequence, if we wish to examine the entire length of a bone, or the length of the spinal column, for instance, it may be necessary to take a series of plates, with different exposures, and to combine all of these in our search for information.

The time at my disposal is so short and the number of advances in surgery is so vast that it would be impossible to give a synopsis of them all. I have, therefore, dwelt in this most cursory manner on only a few of the most important advances made during the past year.

Glancing at these novel procedures we can not help being impressed with the fact that the lines along which surgery is developing show, even more clearly than heretofore, how far the surgeon of today is departing from the type of his early predecessors. The early surgeon, as his name denotes, worked with his hands, χείρ-ἔργον—the chirurgeon, the skilful, handy man—while the surgeon of today not only calls into play the dexterity of his fingers; but in addition thereto exercises his intelligence, his mastery of kindred sciences and puts into practical application the truths of physiology, physiologic chemistry and the results of bacteriologic research. The surgeon of today applies to the solution of the problems which confront him, the experience of the bacteriologist, the chemist, the physicist, and substitutes for empiric methods and for those which have been handed down from generation to generation and accepted as correct in a blind, unthinking way, newer and more scientific proceedings, based upon logical deductions from physical phenomena, and the application of abstract scientific truths to the living being. In the extremely interesting papers which will be brought before you in this meeting you will find this position amply justified.

Medicated Soaps, Savonal.—According to the *Nouveaux Remèdes*, July 24, it has been found that dermatoses are influenced more rapidly by medicated soaps than by salves and pastes, and Müller and Grube have succeeded in producing a soap base which is more stable and efficient than Unna's, etc., as there is no grease in excess. It is made by mixing cold olive-oil, potash lye and alcohol until complete saponification; the fat acids are precipitated with weak hydrochloric acid on glass, and the alkalin mother liquid added until the limpid liquid is perfectly neutralized, when it is evaporated to the consistency of a salve, light green in color, which they call savonal. It is liquefied by adding a certain per cent. of glycerin and aq. dest. and evaporating to a syrup (specific gravity, 1,050 to 1,055). Twenty-three medicated soaps made from it are given with their indications.

MILITARY SURGERY IN TURKEY.

BY N. SENN, M.D., PH.D., LL.D.

PROFESSOR OF PRACTICE OF SURGERY AND CLINICAL SURGERY, RUSH MEDICAL COLLEGE. SURGEON-GENERAL OF ILLINOIS.

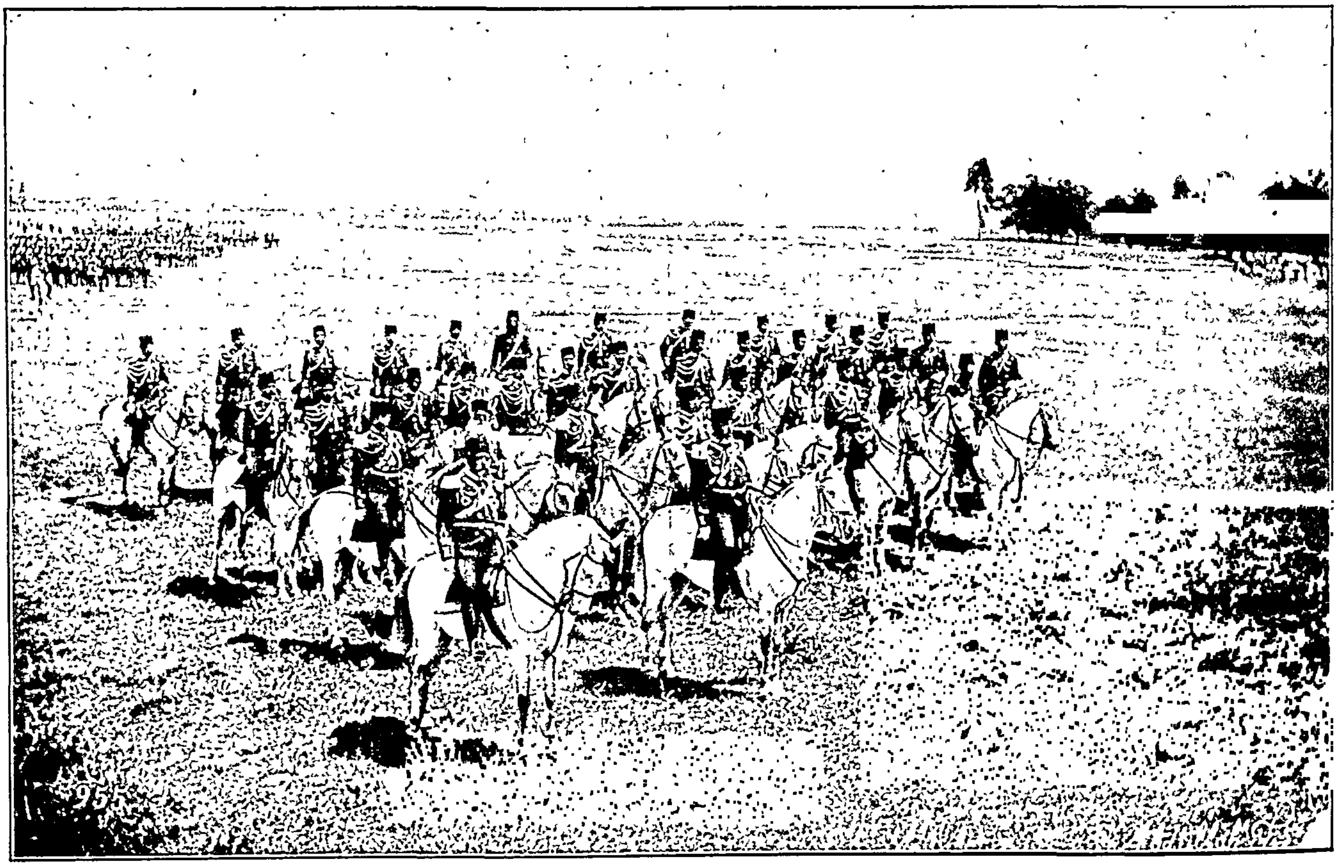
CHICAGO, ILL.

The journey from Athens to Constantinople at this time does not reveal anything that would remind the traveler that a war raged so recently between the two countries. The olive trees, which are seen everywhere, are laden with their oily fruits, and the endless vineyards promise a rich harvest of luscious grapes. The patient donkey carries his burden to the market in slow measured steps as though nothing had disturbed so recently the financial prospects and calculations of his master. In the many fatherless houses the dusky black-eyed children sing and play merrily, ignorant of the violent political eruptions which so recently threatened their lives and homes. The great caravans of camels bringing grain, fruit, spices and oil from distant parts of Asia wind their way along the narrow, crooked streets of Smyrna unmindful of the presence of armed soldiers who are arriving daily from the late seat of war. The few birds that inhabit the rural districts chirp and sing the praises of their Creator with the same regularity and devotion as before the war cry between the two angry nations disturbed the atmosphere in which they breathe and move. The Turk who has returned from the scene of war is a different man from his less fortunate opponent. He is conscious of his victory and all that pertains to it. He holds his head high and in loud and emphatic language relates to admiring crowds the story of the war, the many hairbreadth escapes, the successive victories won, and in prophetic words paints the future glory and prosperity that await his country. The haughty victorious Turk has placed his foot upon the prostrate, trembling little Greece, demanding a war indemnity that they may eventually promise but which they never will be able to pay. The Sultan, intoxicated by the effects of an easily won victory, is defiant and counts himself among the leading rulers of the world. It is impossible to predict the ultimate outcome of the war. What now appears as a defeat for Greece may eventually reflect to her permanent advantage. This faint hope is cherished by all civilized nations and by every lover of art and science.

The average Turk is opposed to innovation and progress. In many respects he resembles the North American Indian. He takes no interest in history and tradition. To him the past is a blank and the future immaterial. His mind is engaged with the present. His inborn wishes and desires are in appropriating day after day, from his surroundings, everything within reach that will satisfy his flesh, leaving his soul to die of gradual starvation. He has no sense for beauty. Turkish architecture has gone into decay. Some of the magnificent mosques erected centuries ago are neglected and crumbling into dust. Science and art never had a foothold in this country, and there are no prospects under the present form of government that they will receive attention for centuries to come. The most auspicious national trait of the Turk is his laziness. Indolence is apparent everywhere. Even the numerous dog population of Constantinople has imbibed this national vice. The miserable half-starved brutes. half wolf and half dog, lie listless and motionless on the stone pavements all day, obstructing sidewalks and streets, and if perchance stepped upon have not sufficient energy to change their position or resent the intrusion in genuine dog fashion. Over all bony prominences the hair and often the skin is worn away at points where the almost lifeless carcass rests against the hard, rough bed of stone. During the night they muster up sufficient courage to prowl about for their scanty food supply and clear their dusty throats by violent efforts at barking. These hideous nightly concerts are the trial and terror of the traveler. The scavenger duty these dogs perform is but an inadequate recompense for the noise and disturbance they create during the night. They are the property of the community and eke out a miserable existence by gathering up the bones and crumbs which fall by the wayside. They are local tramps without a single legitimate function. The fanatic Turk would revenge a wilful injury to one of these beasts as quickly as if it had been inflicted upon a member of his family. The foot passengers and drivers are very careful to walk and drive around them for their own peace and safety as well as to prevent unpleasant street scenes. The dogs know that the Turks are their friends and behave themselves accordingly. The filthy streets and the whole aspect of the business world furnish additional evidences of the widespread indolence that prevails here. If it were not for the influx of immigration from countries where indolence does not exist to the same degree as an epidemic disease, the Turks would have died out long ago from starvation. Constantinople, with its nearly a million of inhabitants, is the most cosmopolitan city in the world. In its streets representatives of all nations can be seen. A free mixture of races for centuries has resulted in staining the skin various shades from an almost pure white to an ebony black color. Similarity of dress is unknown here. From the primitive dress of the original races inhabiting Asia and Africa to the most costly costumes of the Parisian tailor, there are innumerable grades. The red fez is the distinctive headdress of the Turk, whether civilian or soldier. The white and green turban distinguish the Mohammedans in mosque and street. The green turban is an evidence that its wearer is a direct descendant of the great prophet. The Turkish women are in reality married nuns. From the time they reach puberty they are shut out from the gaze of infidels by veil and screen. The windows of every house occupied by a Turk are permanently screened. The women are seldom seen in the streets and public places. In various ways the Turk secures their isolation from the outer world. They are to a certain extent prisoners in their own homes, slaves in more than one sense of the word. The inferior position occupied by women has had its decidedly baneful influence in degrading the male population. It is my opinion that greater freedom of the women would be the very best measure to rouse their sluggish husbands to greater activity and to awaken a keener sense of domestic and national responsibility. Let the women attend the little shops and put the men to work in the fields, workshops and streets, and Turkey would soon be able to pay her debts and become one of the most prosperous countries of Southern Europe.

The Turk as a soldier.—It is not generally known that the material for the Turkish army, with the exception of the medical office, is recruited exclusively from the Mohammedan p[illegible] th[illegible] [illegible]lation.

Every Turkish soldier is a believer in the Mohammedan faith. The military schools and barracks are closed to every Armenian and Greek. The Sultan has no faith in the patriotism of any of his subjects who differ with him in his religious views, and he places his own safe-keeping and the fate of his family exclusively in the hands of the Faithful. The Greeks, Armenians and other nationalities, who are citizens of Turkey but do not confess the faith of Islam, subject to military duty, pay a special tax of twenty piastres every year for the support of the army. The Turkish soldier as a rule is larger and stronger than the Greek soldier. The Greek is temperate in his habits of life as far as alcoholic drinks are concerned. The Turk is an almost complete abstainer. Coffee is his national drink. It would be difficult to find a habitual drunkard anywhere in the country. Masticho, a mild beer, and native wines are about the only alcoholic drinks used, and always with great moderation. The use of tobacco is limited largely to cigarettes and the water-pipe. The men are physically well developed and present the appearances of robust health. Among the officers many handsome men can be seen. The greatest diversity in uniform prevails. The cavalry horses are splendid animals. They are of medium size and high-spirited. The riding equipment is plain but practical. From what I have seen I am not astonished that the Greek feared the Turkish cavalry. The mounted force brought terror and consternation whenever it made an onslaught in earnest. The cavalry and artillery are armed with Winchester rifles, the infantry with Martini and Mauser guns. The Turkish soldier is brave when led by a competent commander and when he sees victory ahead. The faith in his religion takes away his fear of death. On the Turkish side the last war was noted for the quick mobilization of troops and well planned sudden attacks, a repetition of Moltke's methods of warfare. In observing the maneuvers of the troops the hand of German drill-masters can be seen everywhere. The organization of the Turkish army is closely patterned after the German army. The Turkish fleet is in a somewhat deplorable condition, far inferior to that of the Greek fleet. A naval war between Greece and Turkey would be a more equal contest than the late conflict on land. The privates and non-commissioned officers possess a common school education, as education is compulsory in the country. The officers receive a careful military education in the military schools at the expense of the government.



A TROOP OF TURKISH CAVALRY.

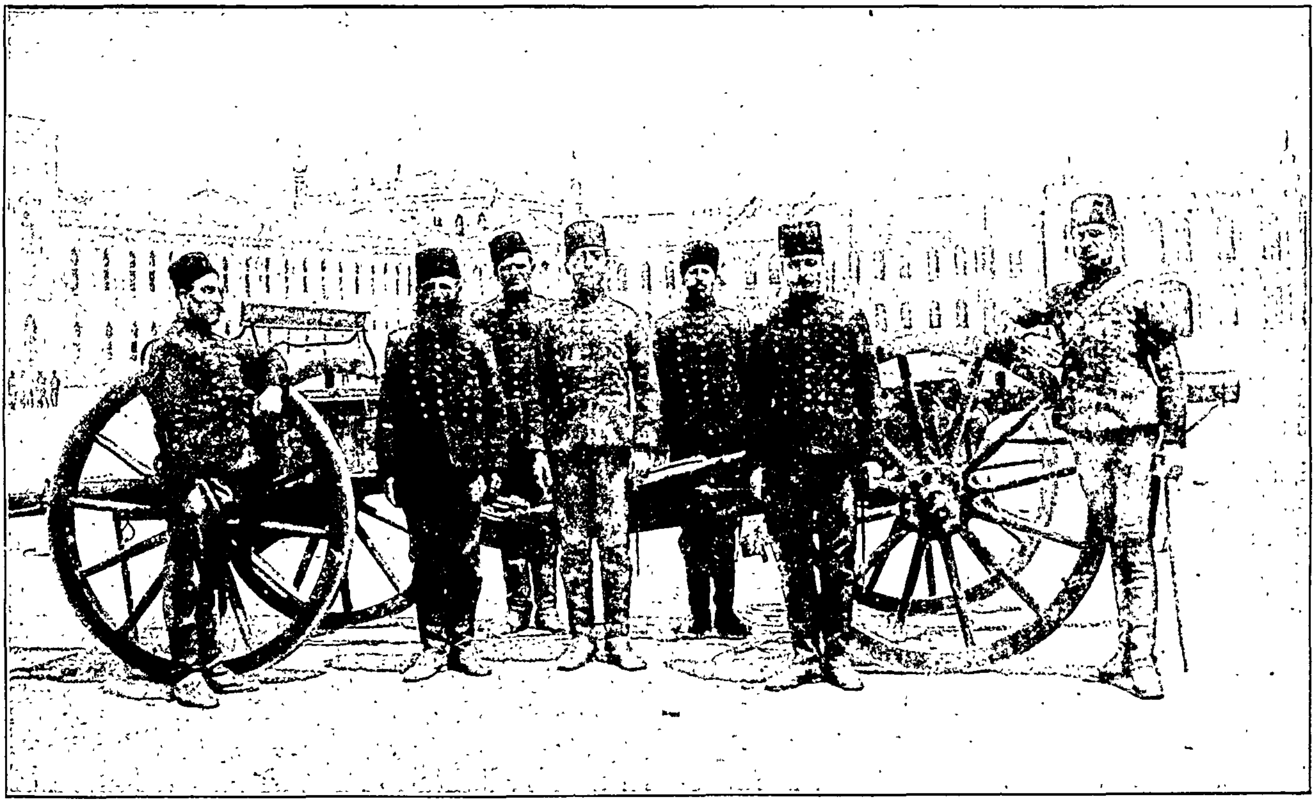
Boy soldiers.—During the late war a number of boys from 13 to 15 years of age, served as volunteers. In one of the military hospitals I was shown three of these little heroes who faced the Greeks on the battlefield. All of them received serious injuries but fortunately recovered. They were anemic and emaciated, but happy in the thought that they had contributed their share in saving their country from foreign invasion. One of the officers took great delight in praising the courage and endurance of these faithful patriots and made the remark that when they did move it was always in the direction of the enemy. Let us hope that the Sultan will recognize their services and that he will see to it that when they leave the hospital it will be with a decoration for heroic conduct, which they can show to their relatives and friends as precious mementoes of their patriotic deeds.

Red Cross societies.—The Red Cross Societies of Germany, Russia and Austria sent physicians, nurses and hospital supplies to the Turkish troops. The

German Red Cross Society was represented by three surgeons and twelve nurses. Russia sent four surgeons and Austria three. Most of the surgeons and nurses did duty in the regular military hospitals under the supervision of the medical staff. The Turkish troops were well supplied with native doctors and there was, therefore, little need of physicians from foreign countries. The English Red Cross sent financial aid. All of the nurses and doctors that remained in the city on my arrival left for their respective homes the next day. The appreciation of the Sultan, of the services rendered by the German branch of the Red Cross Society, was manifested by a gala dinner at the royal palace to the representatives of Germany and Austria the evening before their departure. A notice of this event appeared in one of the daily papers the next day. "The members of the Red Cross Missions sent by their Majesties, the Emperors of Germany and Austria, and who are about to return to their countries on the accomplishment of their task, were entertained at dinner at the Imperial Palace of Yildiz yesterday, Monday. Their excellencies, Mavroyeni Pasha, physician-in-chief of his Imperial Majesty, the Sultan; Munir Pasha, Grand Master of Ceremonies, and Dragoman of the Imperial Divan; and Marshal Shakir Pasha, Chief of the Imperial Military Household, were also present at the dinner. His Majesty was pleased to confer decorations upon his guests, who received them on taking leave after enjoying the Imperial hospitality." Although the Turk is not in sympathy with the work done by the Red Cross societies, he is beginning to appreciate the blessings which these societies bring to the sick and wounded soldiers in time of war irrespective of creed and nationality.

Red Crescent.—During the Crimean war an organization was effected in Turkey, the object of which was to bring aid and comfort to soldiers disabled for duty by sickness or injury. This movement was undoubtedly conceived and fostered by Florence Nightingale, who was then stationed here. After the war the Society remained in existence, but very little interest was taken in its work until after the founding of the Red Cross Association at Geneva during the great War of the Rebellion. The Turks, for obvious reasons, objected to the red cross as the insignia of neutrality of the new society, and adopted in its place the red crescent on a green field. The red crescent has never been popular in Turkey. Not a single member of the army has joined it. It is composed of a few prominent wealthy Turks but the bulk of the list of members is made up of foreigners. The non-combatant soldiers who serve as nurses and litter-bearers wear the red crescent on the left sleeve. The hospital flag bears the same insignia. Practically, the red crescent is equivalent to and is used as a substitute for the red cross in the Turkish Army. During the war just ended the Red Crescent expended 8,000 francs for the relief of the sick and wounded and fitted out a hospital ship which transported many of the wounded from the seat of war to Constantinople. No members of the Red Crescent attended the troops on the battle-field and in the field hospitals. A better organization of the Red Crescent Society is very desirable and should be encouraged and assisted by the Red Cross societies, particularly by those belonging to adjacent European countries.

Medical corps.—The Turkish troops are well supplied with medical officers, who are specially trained for military service. This branch of the military force is open to all nationalities, including the Greeks and Armenians. The medical officers are educated at the expense of the government. The University of Constantinople is attended by about two thousand



TURKISH ARTILLERY.

students, of which number five hundred belong to the Medical Department. The medical course extends over six years, when the candidates for graduation are examined by the Faculty. If the examination proves satisfactory the candidate is reported upon favorably to the Civil Medical Council, in whose hands alone rests the power to grant the degree or licence to practice. As the only university in Turkey is in Constantinople it is somewhat unusual and refreshing to know that the Medical Department contains such a small number of students. The medical student who chooses the military course must pursue his studies the same length of time. The department for medical officers is distinct and the final examination is conducted by a board of examiners composed of seven military surgeons. The president of this board is the Surgeon-General of the Army, who has the rank of a major-general. This board is called the Council of Hygiene and besides deciding upon the merits of the candidates for the medical corps, superintends and controls the work of the medical department of the army. The old custom of training barber-surgeons for the army is still in vogue in Turkey. This low grade of surgeons is composed of men with a limited preliminary education. The barber-surgeon is required to attend lectures and demonstrations for two years before he is permitted to come up for examination prior to his entering the army. His rank in the army is low, his pay scanty and his duties menial. He is allowed to cup, bleed and blister as in years gone by, but is always under the strictest supervision of the military surgeons. He is not allowed to dress a recent wound or prescribe. In a most humble capacity he assists the surgeons in their work. By extraordinary effort and perseverance occasionally such a surgeon is commissioned, when he leaves the barber's trade and is entitled to enter the medical service proper. Two of these surgeons are assigned to each regiment. The medical officers enter the service with the rank and pay of captain. The pay is small and promotion slow unless favored by strong political influences, which here as elsewhere, are the easiest stepping-stones to position and rank. The medical officer in the Turkish army is known by the Æsculapius staff in the center of the narrow shoulder-straps. The rank is indicated by stripes of gold braid on the lower end of the coat sleeve, the stripes running parallel with the sleeve. Officers of high rank are known by the number, color and direction of the stripes. The medical officer, when he enters the army, pledges himself to serve for twenty-six consecutive years, when he can retire with a pension. If, for any reason except disability, he leaves the service before the expiration of this time he is obliged to refund the government for his expenses incurred in obtaining his medical education. That advancement in the medical corps of the army does not always take place in the regular order was made very plain to me when I was introduced to the chief of staff of the Yildiz Military Hospital, who is a pasha with the rank of brigadier general, and is only 27 years old. I was informed later that this rapid advancement was at least in part due to his being the son-in-law of an influential politician who has great influence with the Sultan. It must have been somewhat discouraging to the many gray-haired captains and colonels who have served their country for more than twenty years, to see one so young promoted over their heads. Specialism in military practice is recognized by the Turkish Government. I met two military surgeons, with the rank of colonel, who for years have devoted their whole time and attention to ophthalmology. They attend large wards in the military hospitals set aside for this special kind of work. Both of these men appeared to be familiar with the great advances that have been made during the last twenty-five years in this branch of surgery. There are few men in Turkey who do anything like a large surgical practice. The *furor* of operations has not reached this part of the world. The ovaries and prostate gland are comparatively safe. The Turkish women are not as anxious to be operated upon as their American sisters. The proposal to castrate a Turk for enlargement of the prostate gland would mean personal danger to the would-be operator. The military surgeons are entirely conservative in their work. Unnecessary operating is universally condemned.

Dr. Marie Siebold, a graduate of a Swiss university, is the only female doctor in Turkey. Her sex prevents her from receiving a diploma from the Constantinople University. She has, however, obtained a license to practice her profession. She is an earnest student, a careful and able practitioner and, while not fully recognized by her male colleagues, she is certainly fully their equal. Dr. Siebold has seen military surgery, but during the last war took no active part.

Hospital corps.—The hospital corps is composed of 3,000 non-combatants specially trained for the transportation of the wounded and the care of the sick; litter bearers, detailed as emergency demands, and hospital stewards. The hospital stewards are graduates in pharmacy and are enlisted as such after having passed a satisfactory examination, The army is supplied with 8 ambulances and 200 litters. This equipment for the transportation of sick and wounded during the late war proved inadequate and the most of the wounded had to be carried from the battlefield to the field hospitals on mules, donkeys and rough carts. It is said that many cases of penetrating wounds of the abdomen were strapped on the back of donkeys and died before reaching the hospital. The dressing materials which I saw in the different military hospitals were either of French or German manufacture. Considering the many modern improvements which have been made in the arms and equipments of the Turkish army, it is to be regretted that so little money has been spent in bringing the hospital corps up to the high standard of the present requirements in field and hospital practice.

Military hospitals.—All of the field-hospitals were either buildings used for this purpose temporarily or hospital tents. The permanent military hospitals in Constantinople are large and commodious structures. Everyone is located on an eminence surrounded by ample grounds beautified by semi-tropical trees and flowers.

Yildiz Hospital.—This structure embraces twenty-two barracks and overlooks the palace of the present Sultan. Before the war a few old barracks furnished ample accommodation for the sick of the military force in that part of the city. When the war broke out new barracks were built, and in less than four weeks it furnished room and ample accommodations for 1,000 patients. This is the hospital to which most of the wounded were brought and in which most of the operations were performed. At the time of my visit it contained 900 patients, most of them surgical.

It is under the charge of Djemil Pasha, who is chief of the large medical staff. The surgeon-in-chief is only 27 years of age and is a graduate of Paris. He is a fine-looking man, a polished gentleman and is said to be the best military surgeon in Turkey. The oculist in this institution is Professor Behdjet, who, in the army has the rank of colonel. Colonel Behdjet has a large number of cases under his care and has made some very interesting observations on wounds of the eyeball and orbit. He has had under his personal observation twenty-two cases of traumatic destruction of the eye without a single case of sympathetic implication of the opposite organ, although in a number of cases enucleation was refused. In several cases shown the injured eyeball had been removed, the patients wearing a glass eye with most excellent cosmetic result. It is a somewhat singular circumstance that in all cases it was the right eye which was injured. One of the barracks is used exclusively for operative work. There are two operating rooms, one at each end of the building, one of which is used for aseptic the other for infected cases. Attached to each of the operating rooms is a small ward with four beds where the patients who have been operated on are taken care of until they have recovered from the immediate effects of the operation. The operating rooms are supplied with all the materials and instruments for aseptic work. Until recently two barracks were in charge of four German female nurses belonging to the German branch of the Red Cross Society. The patients are well fed. The day I visited the hospital the bill of fare for dinner included soup, rice, spaghetti, roast mutton and squash. The evening meal includes vegetables. The coffee and bread are better than in the average restaurant and hotel in the city. Wine is served only when prescribed by the attending surgeon.

Haidar Pasha Hospital.—This hospital is one of the oldest in the city. It was erected a few years before the Crimean war. It is located across the Bosphorus in Scutari, is an enormous structure with a capacity for 1,000 patients, and is surrounded by beautiful grounds extensively supplied with trees, shrubs and plants. This hospital has been made famous by the work of Florence Nightingale. It is here that during the Crimean war so many soldiers received her skilful and faithful services. I was somewhat astonished not to find a reminder of her unselfish humanitarian work. The Turks speak of her with great reverence and respect, and in many ways manifest their highest esteem for her, but have done nothing, as far as I could see, to commemorate her memory. The Turkish military hospitals are closed to the outside world. All foreigners have to obtain permission through the minister of war to visit them. The doors once open every possible courtesy is shown from the highest to the lowest officials. Coffee is invariably served at the conclusion of the visit. Soldiers, officers and visitors are expected to smoke cigarettes whenever they feel inclined to do so. As the doors and windows are always wide open this general practice does not vitiate the atmosphere. The Turkish soldier eyes the visitor with great interest and is always willing to subject himself for examination. He is especially pleased to exhibit the effects and marks of recent gunshot injuries. The Haidar Pasha Hospital is now occupied by a large number of convalescents, medical and eye cases; it contains but few cases of recent gunshot injuries. The ophthalmic department is in charge of Col. Dicran Bey Adjeinian; it now numbers 140 patients. Colonel Adjeinian is a graduate of Berlin and devotes his whole attention to diseases of the eye. He has had a large experience in the treatment of ectropium. During the last five years he has operated on forty-two cases by the use of Thiersch's grafts. The contracting scar is excised; the margin of the wound away from the free border of the eyelid is transfixed at two points with a needle armed with silk. The silk sutures are fastened upon the surface of the skin with collodium in such a way as to secure extension, thus widening the wound as far as possible. The raw surface is then covered under strictest antiseptic precautions, with one Thiersch graft. The graft is covered with a few layers of gauze wrung out of a 1 to 5000 corrosive sublimate solution, over which a thick compress of absorbent cotton is placed, the whole confined in place with an ordinary or gauze bandage. In applying the dressing, care is exercised to secure equable compression of the wound. The dressing remains for six days. He has operated by this method forty-two times with twenty-seven perfect, ten partial successes and five failures. He claims that in the cases which terminated favorably there was no tendency to relapse, and that the functional as well as the cosmetic results were excellent. The operating theater is well lighted and furnishes all the necessary equipments for aseptic work.

Formerly typhoid fever was common, but since the water supply has been changed it has almost disappeared. The drinking water is now brought in casks from the mountains. The nursing is done exclusively by male nurses.

Kumuch Sou Hospital.—This is the third large military hospital in Constantinople. It is used for medical and surgical cases. It has about the same number of beds as the Haidar Pasha. Each of these hospitals is in charge of a chief of staff, assisted by the requisite number of surgeons.

Killed and wounded of the late war.—It has been impossible for me to obtain reliable data relating to the strength of the Turkish army or the number engaged in the last war. From what I could ascertain the war footing of Turkey is in the neighborhood of 750,000, and of this number about 100,000 to 150,000 were sent to the front. At the present time Constantinople is full of soldiers. All of the barracks are crowded and nothing indicates that a large army still occupies Thessaly. Last Friday I had the pleasure of seeing the Sultan drive from his palace to the mosque, which he attends every week on the same day and at the same hour. This is always a gala day for the military. On this day at least 10,000 soldiers in full dress, representing the infantry, cavalry and navy, were drawn up to do honor to their chief and protect his person when outside of his prison palace. The officers and soldiers made a splendid appearance and the whole exercises passed off with a regularity and dispatch that would do credit to any country. The cavalry attracted special attention. The soldiers for this branch of the military service are selected with special care and the horses are the finest I have ever seen. The Greeks used large caliber guns and lead projectiles. The wounds on the Turkish side were all inflicted by large lead bullets. Although the Greeks were defeated, the victory seems to have cost many lives. The Turkish army lost 1,150 killed and 2,850 wounded; many of the latter died subsequently. The wounded were dressed on the field and were conveyed as quickly as possible by such means as could be secured to the field hospitals. A good many died here from the immediate and remote effects of their injuries. Those that could be transported were taken either by boat or railway to Constantinople, where ample room and accommodations were furnished by the regular military hospitals. I was given an opportunity to see and examine at least one thousand cases of gunshot injuries, most of them on the way to recovery. Infection was much more frequent on the Turkish than on the Greek side. A partial explanation for this difference is probably furnished by the size of the bullets in use and the difference in distance in conveying the wounded to the permanent hospitals. I took notes of a few cases of interest of which I will give brief accounts.

Case 1.—Secondary resection of shoulder joint. Bullet entered in front, passed through the head of the humerus and escaped behind. Resection of about three inches of the upper end of the bone was made, anterior and posterior incisions, and pieces of cloth removed from the wound. Infection. Fistulous opening remained in front; the posterior incision healed. Very little use of arm. Patient's general condition good.

Case 2.—Gunshot wound of knee joint. Bullet comminuted internal condyle of the femur and opened the joint. Extraction of bullet and atypical resection of joint in the field-hospital. Primary healing. Joint partially anchylosed, with leg in useful position.

Case 3.—Bullet wound of orbit. Bullet entered over the right superciliary ridge, passed backward, outward and downward, and escaped below and in front of external ear. Wound healed and patient is wearing an artificial eye with comfort.

Case 4.—Gunshot wound of knee joint. Bullet located by the use of the Roentgen ray. No suppuration. Incision of joint on both sides and removal of bullet. Primary healing of wounds. Motion of joint almost perfect.

Case 5.—Gunshot fracture of the spinous process at the junction of the dorsal with the lumbar vertebræ. Paraplegia complete immediately after receipt of injury. Paralysis remained until laminectomy at the seat of injury was performed. Operation followed by prompt improvement. Patient is now able to walk without the use of crutches. Depression of fractured vertebral arch was found to be the cause of the paralysis.

Case 6.—Typical resection of shoulder joint for comminuted gunshot fracture of head of humerus. Wounds of entrance and exit were enlarged, through which the fragments and projecting pieces of bone were removed. Wounds healed. Fair degree of motion.

Case 7.—Gunshot injury of shoulder joint. Bullet passed obliquely through joint. Anterior and posterior incisions made through which loose fragments were removed. Operation performed in field-hospital. Slight infection. Fistulous opening remains behind; anterior incision healed by primary intention. Use of arm very limited.

Case 8.—Gunshot wound of shoulder joint. Débridement in the field hospital. Rapid healing of wounds of entrance and exit. Function of arm returning gradually.

Case 9.—Gunshot injury of axillary plexus. Bullet entered below the level of the shoulder joint and on the inside of the surgical neck of the humerus, and escaped behind, half way between the scapula and the dorsal spine. Complete paralysis. Patient complains of great pain, which he refers to the paralyzed limb and caused probably by a traumatic neuritis or neuroma. Secondary nerve suture is being considered.

Case 10.—Gunshot injury of elbow joint. Bullet passed obliquely through the joint, fracturing the internal condyle of the humerus. Primary atypical resection of joint. Infection. Fistulous opening remains behind the joint. The injured parts were exposed by a posterior bayonet-shaped incision. Active motion, none: passive motion, slight.

Case 11.—Gunshot injury of spine in lumbar region. Paralysis complete from the beginning. Bullet remains in the tissues. Wound healed. Cord has probably been crushed by the bullet or fragments of bone.

Case 12.—Resection of knee joint for gunshot injury. Great comminution of articular ends of femur and tibia. Primary resection. Healing of wound without suppuration. Consolidation not complete after two and a half months.

Case 13.—Secondary resection of knee joint for gunshot injury. Slight infection. Healing by granulation. Limb in good position. Bony union quite firm.

Case 14.—Gunshot injury of right crest of ilium. Partial resection for the purpose of removing bullet and loose fragments. Wound healed. Abdominal cavity not opened.

Case 15.—Loss of right eye caused by gunshot injury; loss of a portion of the orbital arch. Wound healed. Patient wearing artificial eye with comfort.

Case 16.—Retrobulbar gunshot wound of right eye. Bullet entered orbit, passed behind the eyeball and escaped in front of the external meatus on the same side. Traumatic optic neuritis destroyed the eyesight completely. Patient refuses enucleation. No sympathetic complications.

Case 17.—Loss of right eye from gunshot injury. Enucleation of stump. Complete healing of wound. Wears artificial eye without any inconvenience.

Case 18.—Gunshot wound of right groin. Bullet entered one inch above Poupart's ligament to the under side of the large blood vessels and escaped through the perineum on the same side. Intestinal fistula remains. Use of limb not much impaired.

Case 19.—Volunteer, 13 years old. Wound of right iliac region. Infection followed the injury and resulted in the formation of a large perityphlitic abscess, which was later opened and drained. Rapid recovery. Boy much emaciated and very anemic, but able to walk about the hospital grounds.

Case 20.—Volunteer, 14 years old. Gunshot wound of arm. Bullet passed from behind backward about an inch to the inside of the surgical neck of the humerus. Healing of wound by primary intention. Little or no impairment of function of the muscles of the arm.

Case 21.—Volunteer, 13 years old. Flesh wound of leg. Healing of wound under primary dressing.

Case 22.—Gunshot injury of skull. Primary operation. Removal of depressed fragments of bone. Wound healed leaving a pulsating cranial defect.

Case 23.—Secondary amputation of arm for gunshot wound. Stump healing by granulation.

Case 24.—Gunshot wound of superior maxilla. Partial secondary resection. Wound healing by granulation.

Case 25.—Partial resection of lower jaw for comminuted gunshot fracture. Considerable deformity.

Case 26.—Gunshot fracture of humerus. Great loss of bone caused by the injury and later by an operation for the removal of sequestra. Although periosteum was saved there is no callus at the end of two months, and a false joint without further interference will be inevitable. No nerve injury.

Case 27.—Gunshot wound of right groin. Abscess formation. Incision and drainage. Rapid improvement. Fistula remains. No intestinal complications.

Case 28.—Resection of shoulder joint. Wounds healed. Arm remains almost useless. Great muscular atrophy.

Case 29.—Gunshot injury of skull. Removal of fragments of bone. No focal symptom. Wound healed leaving a pulsating scar.

Case 30.—Loss of right eye from gunshot wound. Wound healed. Wearing artificial eye.

Case 31.—Gunshot wound of nose and hard palate. Bullet entered the center of the bridge of the nose and entered the mouth through the hard palate. Patient spit out the bullet from the mouth immediately upon the receipt of the injury. The perforation in the hard palate was closed by a plastic operation. External wound healed. Saddle nose.

Case 32.—Gunshot wound of face and lower jaw. Bullet entered over the ascending ramus of the lower jaw on the right side, entered the mouth, perforated the tongue and escaped through the mouth. A suppurating fistula communicating with the jaw remained. Recently this fistulous tract was laid open and a detached tooth was removed, after which the fistula closed rapidly and permanently.

Case 33.—Gunshot wound of ascending ramus of jaw on right side. Bullet chipped away part of the bone and lodged behind near the spine, from where it was successfully removed by a tedious and difficult operation. Movements of lower jaw limited, otherwise no functional disturbances.

Case 34.—Resection of elbow for gunshot injury. Secondary operation through posterior bayonet incision. Fistulous openings and considerable swelling of soft parts remain. Muscles of arm and forearm much atrophied.

Trephining for traumatic abscess of the brain.—Djemil Pasha, of the Yildiz Hospital, informed me that trephining for abscess of the brain following gunshot injuries with lodgement of the bullet in the cranial cavity, was performed three times. In all of the cases the indications for the operation were furnished by the intracranial suppuration. In all of the cases the abscess was found and the bullet removed. Two of the cases recovered and one died.

Constantinople, Aug. 6, 1897.

THE NERVE ELEMENT IN SURGICAL PATHOLOGY.

Presented to the Section on Surgery and Anatomy, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY J. McFADDEN GASTON, M.D.
ATLANTA, GA.

The interlacing of the nerves with the different structures of the body gives energy to every vital organ in health and aggravates their disorder in disease.

To understand the correlation of the nerves and capillaries with the internal viscera presupposes a knowledge of the relation of the cerebro-spinal nerves with the ganglionic and vasomotor nerves. The outgrowth of the operation of the excito-motor, the excito-secretory and the excito-dynamic functions of the nervous system upon the different structures in their physiologic condition, prepares the mind to appreciate the great effects of vitiated actions of the nerves under their pathologic derangement.

The organic changes in nerve tissues are pre-eminently characteristic of the direct involvement of the nerve element, and the development of neuromata in the course of the nerve trunks illustrates the part taken by the nervous system in surgical pathology.

Neuralgia, in all its protean forms, is not a mere functional derangement of the nerve centers, but depends in most cases upon local modifications resulting from inflammatory action in the neurolemma or parenchymatous structure of the affected nerve. It may also exist, in a spurious form, connected with compression of the trunk, or from cicatricial adhesions after operations. The impression that contraction of nerves may give rise to painful developments has led to nerve stretching as a remedial agent, but little advantage has attended this procedure, and the idea that nerve shortening is pathognomonic is thus negatived.

Facial neuralgia has been traced to the Gasserian ganglion, and successfully attacked in some cases by operative measures involving the temporal bone, or in other cases by ligation of the common carotid artery.

Rheumatic complications of a most painful form, involving various regions of the body, are dependent upon the nerve supply to the part; and the acute sensibility of such structures renders anodynes of the greatest importance in the treatment of such disorders of the different organs.

Inflammatory processes, wherever located, are accompanied with pain, from the entrance of the sensory branches of the nerves into the organs; and the means which are adopted for the relief of the inflammation must include the control of the neurotic disturbance by combating this pain.

It is a fair inference that all agencies for the mitigation of pain have a curative effect upon the structures involved in disease.

The reciprocal influence of body and mind, in the progress of most physical disorders, depends upon their connection through the nervous system.

The psychic characteristics of neurotic patients must be taken into account in the management of surgical disorders, just as in medical cases, and much depends on the mental state of one who has undergone a grave surgical operation. The enervating influence of depression of spirits on the nervous system should be obviated by pleasant surroundings in the after-treatment. While these manifestations of the nerve influence in surgical disorders indicate the relation of cause and effect, it is to another mode of action on the part of the nervous system that I wish to draw especial attention.

In my address as President of the Southern Surgical and Gynecological Association, in 1892, the following points were presented: Observation of the changes resulting from inflammatory processes should be accompanied by a study of those modifications impressed upon the tissues by impairment or undue activity of the nerve element which enters into their composition. That many operators fail to take the nervous system into account in their surgical pathology, shows a lack of due consideration of the surroundings of a patient. It may be that a skilful operator is not qualified for the highest attainment in surgery, from lack of proper precaution in proceeding with an operation, or subsequently.

The aim of the surgeon should be a due comprehension of abnormality in the structures of the part involved, and his end be to afford relief with the least possible injury to the organ or member which is the seat of disorder.

A proper recognition of the scope of surgery and medicine assigns to them respectively the organic and functional disorders of the system; when organic changes ensue, whether demanding the use of medication or a resort to operative measures, the case comes within the field of surgery.

With our deficient knowledge of the etiologic factor in that condition known as shock, I am inclined to the view that a continuous baleful influence is propagated to the nerve centers from the disintegration of the structures involved, and that this may be modified favorably by amputation with a clean incision through sound tissues above the point of injury, very soon after such violence to the parts. A proper appreciation of the participation of the ganglionic nervous system in shock, should impress the great urgency of arresting the morbific influence by removing the cause.

The motor and sensory branches of the cerebro-spinal system of nerves are so related to the ganglionic nerves that an impression is propagated from the former to the latter by every change resulting from violence. We are therefore prepared to expect surgical shock involving the organic nerve centers from any accident accompanied by great laceration and contusion of the soft parts, or comminuted fracture of bones of the lower extremities.

To a greater or less extent the injury inflicted on the superficial cutaneous nerve fibrils is extended to the internal organs by the correlation of the nerves and capillaries with the viscera, and any extensive impression over the surface, however slight, is attended by marked vital depression. A striking illustration of this fact is presented in the grave effect of slight superficial burns extending over a large surface, and the serious consequences of the stings of wasps or bees over any considerable part of the body, though each is insignificant in itself. The notable effects observed from cups, sinapisms and blisters upon the skin are likewise due to the sympathies established through this channel of the nerves.

A dynamic element which characterizes the mutual dependence of the superficial and deep-seated structures is apparent from the fact that, under some conditions of the organism, the irritant fails to manifest its influence on the tissues. The mustard or cantharides may be applied to the surface for the ordinary period, under such a depressing modification of vitality, without producing any perceptible effect. Yet, when a change has been effected in the state of the organization, normal susceptibility is restored.

The natural sensibility returns to the skin and irritation, with the consequent inflammation, manifests itself in the parts where no effect was previously observed. A rigid investigation of the nerve element implicated in this condition is required by those who would fathom this lack of the excito-dynamic function of the nerves.

The developments growing out of the relation of certain portions of the brain to the distribution of nerves to different parts of the body, are calculated to impress the profession more than any of the other advances of surgery within the last decade. It is to Horsley especially that we are indebted for localizing the brain centers connected with the distribution of nerves, and this fact has enabled surgeons to fix upon the sites of tumors and abscesses in various fissures and in the substance of the brain, by tracing the abnormalities of the branches of the nerves back to their origin. While this knowledge has served to guide the surgeon in chronic cases, little progress has been made in acute cases attended with blood clot or with localized inflammation. It is stated, in the *Medical News*, that Oppenheim emphasizes the difficulty of differential diagnosis in traumatic brain abscesses, which may be confounded with traumatic meningitis, apoplexy, encephalitis, tumor, epilepsy, traumatic neurosis, etc.

One of the great practical questions of the day which concerns every surgeon, is the consideration of traumatic neurosis, and, notwithstanding the numerous papers written for its elucidation, the decision is still involved in great obscurity. Even in cases where there is no motive for deception on the part of a patient, there are such a variety of neurotic troubles growing out of physical injuries, that depend upon the psychic impressions of the subject, that it is difficult to determine anything from subjective symptoms. There is frequently a notable absence of definite objective symptoms, and often a strong influence for simulation, which afford obstacles to forming an opinion in a given case. In an article by Dr. A. L. Hall,[1] we learn that "a correct diagnosis is best obtained from a reliable account of the accident, the history of the previous state of the patient, the presence of surgical troubles, and the existence of a stable well defined organized symptom complex."

There is a nervous disturbance which is attributed to so many different causes and relieved by such diverse means of treatment as to leave a doubt whether it should be classed with the neuroses or considered as an inflammatory process. This is known as multiple neuritis. The symptoms, according to Gowers, are of three classes—motor weakness, sensory disturbance and inco-ordination. According to the predominance of one or another of these, we have a motor, a sensory, and an atactic form of the disease. In an article by Dr. Charles Lewis Allen, it is stated that neuropathic constitution and exposure undoubtedly predispose to an attack. It begins with tingling and numbness in the finger-tips and soles of the feet. Sooner or later this spreads up the limb, and is followed by pain and loss of power, the legs suffering earlier and more than the arms, and often exclusively. The pain is located along the nerves and in the muscles.[2]

The involvement of the nervous system in epilepsy, is of such a nature that its effects are to a large extent dependent upon a cumulative influence, which leads to periodic explosions. It is held by Hughlings Jackson, that the phenomena of epilepsy are all explained by a discharging lesion of the cells of the gray matter, and that the disease affects the motor centers and does not often have its primary seat in the medulla.

The nerve-cells are likened to so many Leyden jars which generate the electricity. Thus the explosion is due to a sudden diminution of resistance by which the pent-up nerve force is released, thus causing the epileptic phenomena. It so turned out that a similar solution of the intricate problem of the causation of this intermittent nervous disease was presented by me, before I knew anything of the theory of Hughlings Jackson, in a paper written in 1882, and read before the Medical Association of Georgia in 1884.

In illustration of my claim of originality I give the following quotation from my paper: The periodic and irregular exhibitions of nervous disturbance involves the most intricate etiologic conditions in the history of the pathology of this class of diseases.

Why the cause should be operative at one time and not manifested at another, is only capable of explanation on the basis of an accumulation of energy, which leads as it were, to an explosion, with a capacity of reproductions at certain intervals or at indefinite and irregular periods. The calm which is observed between the convulsions of epilepsy is not in any sense an absence of the disturbing cause, but an occasion for its gradual development until it shall have reached a force that breaks forth in the paroxysm, which is *sui generis*. The charge becoming completed, there is a forcible eruption of the excito-dynamic energy of the nerve centers.

Another phase of morbid development growing out of the transmission of local irritation or inflammation to other parts through the nerves, comes under the head of reflex disturbance. While the sympathies of certain local developments, especially those connected with the genitals of male and female children, with the distribution of the nerves to various organs of the body, are evident, the link of association is somewhat obscure. It is true that the practical results of surgical operations based upon this view have gone toward the confirmation of such a relation, and removal of the prepuce and clitoris, in the respective sexes, have proved successful in relieving the neurotic disturbances which are attributed to the local troubles.

The eruption of the teeth in children, and even wisdom teeth at a later period in life, are attended with neurotic disturbances of a marked character, which are promptly relieved, at times, by cutting through the gums.

These various manifestations of the intimate relations of the nerves with the different structures of the body open up the way for comprehending the role of nerve element in surgical pathology.

The development of traumatic neuritis is the most common complication of surgical cases; and there is rarely any extensive lesion which is not accompanied with more or less pain dependent upon inflammation of the nerve or its neurolemma. The irritation of the peripheral branch of a nerve may set up a train of disorders terminating in tetanus or lymphangitis, and the serious consequences of both these affections are well known.

[1] Medical Record, p. 436, Sept. 26, 1896.

[2] Medical Record, p. 587, April 24, 1897.

In the latter condition, not only the lymphatic ducts become implicated but ganglions are involved in the inflammatory process, and suppuration is set up in the course of the lymphtics, with the characteristic features of pyemia, terminating in multiple abscesses in various portions of the body.

The subcutaneous use of simple distilled water has been resorted to with apparent effect upon the nervous system, and this proves a very delicate response of the nerves to the action of agents introduced hypodermically. The marked results of subcutaneous injections depend upon the connection of the nerve fibrils and the capillaries with the spinal and the ganglionic system of nerves.

The transmission of cutaneous modifications to the internal organs becomes, in numerous instances, simply the expression or delivery of a dynamic influence which operates through the nerves. Instead of a local irritation, as might be anticipated from the topical application, there is a general influence upon the organism corresponding to the special property of the agent employed, and we must attribute the effect to the conduction of medicinal powers from the point of introduction through the various channels of communication with the dependent structures.

To summarize the chief features of practical importance in the relations of the nervous system to other structures involved in surgery, we make the following deductions:

1. The cutaneous development of the minute branches of the cerebro-spinal system of nerves and the ganglionic ramifications of the gr[illegible] are so related to the capillaries, as to [illegible]rocal action and reaction between them and the great nerve centers.

2. The vaso-motor nerves are so intimately linked with the excito-motor, the excito-secretory and excito-dynamic system of nerves that impressions made through the superficial afferent nerves are conveyed to all the corporeal structures and tissues so as to produce their effects upon the different organs.

3. Reflex phenomena depend on a complex interchange of local pathologic conditions with the nervous ramifications to remote parts of the body.

4. The fountain head of energy for all the functions lies in the nerve centers; and by controlling emanations from this source of power, the vital forces will be propagated, with regularity and uniformity, to all the remote parts of the physical organization. On the contrary, a harmful influence disseminated from the nerve centers entails disease in the different organs.

5. The means to be adopted for averting injurious impressions on the nerve centers, and the measures to be used for the correction of their derangement, make up the whole prophylactic agency of hygiene, and include all the therapeutic appliances in the treatment of diseases, as well as the application of surgical measures.

6. Close observation of the various modifications of the nerve element on the physical organism should reveal its direct influence in surgical pathology, and lead the surgeon to the adoption of proper means of relief.

THE OPERATIVE TREATMENT IN OCCLUSION OF THE JAWS.

Presented to the Section on Surgery and Anatomy, at the Forty-eighth Annual Meeting of the American Medical Association, held at Philadelphia, June 1-4, 1897.

BY J. EWING MEARS, M.D.
PHILADELPHIA, PA.

At the meeting of the American Surgical Association June 1, 1883, I read a paper on this subject and endeavored to collect all the information which then existed with regard to the procedures which had been in use from the first, for the relief of a condition which may at least be described as one very distressing to the patient. Mr. Christopher Heath of London in the "Jacksonian Prize Essay" of 1867 recorded cases in which he had performed operations for the relief of jaw-closure, and in a chapter devoted to the subject collated the work of others up to that date. According to Mr. Heath's statements, English text-books on surgery were remarkably barren of any information on the subject. He alludes to a reference of Mr. Cooper in his Surgical Dictionary, to a case treated by Dr. Valentine Mott in 1831, in which an operation was performed for closure of an opening in the cheek caused by sloughing and accompanied by closure of the jaws. In the edition of Cooper's Dictionary issued in 1861, closure of the jaws is described as occurring "after sloughing of the cheeks and gums from profuse salivation, the cicatricial bands being so rigid as scarcely to allow of the separation of the teeth." By far the most complete account is given in the first edition of Gross' "Surgery." This eminent surgeon had a favorable opportunity for studying the affection during his residence at Louisville, Ky., where, in college and hospital clinics, he was enabled to acquire a large experience owing to the prevalence of this condition due to the administration of calomel in excessive doses in the southwestern sections of the country.

The affection occurs in two forms—the spasmodic or temporary, and the chronic or permanent. The former usually occurs in connection with some condition which affects the motor filaments of the third division of the fifth nerve, causing spasmodic contraction of the elevator muscles of the lower jaw. Among the causes may be enumerated the delayed or difficult eruption of the third molar or wisdom tooth of the lower jaw, the development of tumors from the external surface of the ramus and body of the lower jaw, alveolar abscess in connection with the posterior teeth, necrosis of the jaws, suppurative tonsillitis, and I have observed the condition to follow operations on the lower jaw when performed in the molar region. It may be proper to include under the temporary form of jaw-closure the condition which occurs in connection with attacks of tetanus. This form differs from those described above by reason of the fact that the jaw-closure is one among other symptoms which are present.

The treatment of the temporary form of jaw-closure consists in the removal of the causes. When dependent upon the impeded eruption of the wisdom tooth, the mouth should be opened by levers, the patient being placed under the influence of an anesthetic, and the second molar tooth should be extracted so as to afford space for the third molar, or as the latter is not infrequently found to be an imperfectly developed tooth, the offending organ should be removed. Where tumors, necrosis and alveolar abscesses exist as causes, the treatment is obvious. For the relief of trismus, which is so prominent a symptom of tetanus, remedies which are efficient in controlling the general condition will afford relief.

Permanet jaw-closure may be due to conditions which attach the alveolar processes of the jaws firmly together, or to those involving the temporo-maxillary articulation. Union of the processes of the jaws may be accomplished through the formation of cicatricial tissue or of an osseous band. The formation of the cicatricial tissue is due to inflammation attacking a portion or the entire buccal mucous membrane. In these cases the inflammation may be due to ordinary causes or, as was most frequently the case in former years, be created by the excessive use of calomel producing severe ptyalism, and, as a rule, it occured in children. As a result of its occurrence at an early period of life the growth of the lower jaw and the associated structures is very markedly interfered with. I have observed this condition in many of the cases which have come under my observation. The formation of the osseous band may depend upon injury to the parts or arthritic inflammation leading to a a deposit of plastic matter and the conversion of this substance into fibrous, cartilaginous or osseous tissue. This bridge of bone may extend from the lower to the upper jaw or from the lower jaw to the temporal bone.

Closure of the jaws due to anchylosis of the temporo-maxillary articulation may occur as a result of inflammation attacking the joint, or of injury leading subsequently to inflammation which results in the formation of fibrous or osseous deposits. Very frequently the inflammatory action which is responsible for the obliteration of the function of the joints is rheumatic in character, and the condition is found to exist largely in those who suffer from rheumatic affections. It may also occur as the result of inflammation due to blows or concussions. The most frequent cause, according to my observation in traumatic cases, is the occurrence of fracture involving the neck of the condyle and which has been unrecognized. Such condition shortly leads to closure of the jaws, and this finally becomes permanent.

The pathologic conditions which produce jaw-closure may exist on one or both sides, that is, it may be unilateral or bilateral. In cases of closure due to the presence of cicatricial tissue or osseous band the diagnosis may be readily made by inspection of the parts and the introduction of the finger into the buccal spaces. When the temporo-maxillary articulation is involved the diagnosis may be somewhat more difficult, by reason of the inability of the surgeon to decide whether the joint is at all affected, the closure being possibly due to a contracted or rigid condition of the levator muscles of the jaw, and also, when the affection is unilateral, to decide on which side the fault rests. As complete a history as possible should be obtained in every case and both inspection and palpation of the joints should be practiced. The index finger of one hand should be passed into the mouth and carried as fas as possible on the inner surface of the ramus of the jaw toward the joint, and the index finger of the other hand should be placed over the joint externally. The patient should then be requested to make an effort to move the jaw so as to ascertain whether any motion exists in the joint. This manipulation should be made on both sides in order to determine in which joint motion may exist. The history of the case, in the event of the occurrence of injury to the joint or fracture of the neck of the condyle, may give information as to the joint involved, but this can not always be depended on. Deviation of the lower jaw to the affected side may sometimes exist, especially when anchylosis has been preceded by some inflammation. In such cases this condition aids diagnosis.

Under the improved methods of treatment the prognosis of jaw-closure may be regarded as favorable. Even in the most inveterate cases, in which the entire buccal spaces on both sides have been obliterated by masses of nodular tissue, operative treatment promises relief.

The treatment of jaw-closure due to the formation of cicatricial tissue has claimed much attention and has taxed the skill and ingenuity of surgeons from the beginning. At first, efforts were directed simply to the division of the tissue and the use, subsequently, of levers varying in power, by which the jaws were separated. The rapid reformation of the nodular tissue, with augmented induration and contractile power, rendered this method futile. Excision of the mass was then practiced with the hope of securing normal membrane in place of the tissue removed. This plan was not successful and was followed by a suggestion, if not the practice, of excision and transplantation of mucous membrane or of integument into the denuded buccal space, taking the flap of integument from so distant a point as the arm. Failure attended these efforts, and in 1851 Professor Esmarch of Kiel read an essay before the congress at Göttingen on the "Treatment of Closure of the Jaws from Cicatrices," in which he advocated the formation of a false joint in front of the cicatricial mass by the excision of a segment of bone of such size as to prevent union of the divided end and the operation was performed by an external incision along the base of the jaw. Professor Rizzoli of Bologna, in 1857, operated for permanent contraction of the jaws by a simple division of the lower jaw in front of the cicatrix, using for that purpose powerful forceps applied within the mouth. In order to prevent union a piece of gutta-percha was inserted between the cut surfaces of the bone, which procedure, it is stated, was accomplished successfully. By these two methods of operation one half of the mouth could be opened slightly, and thus far the operation was regarded as successful. The manifest objections to these methods were: 1. The slight extent to which only a portion of the mouth could be opened. 2. The formation of a disfiguring cicatrix, especially objectionable in females, when the external incision is employed. 3. The fact that this method could not be employed when both buccal spaces were occupied by cicatricial tissue.

Having failed, as others before me had done, by the employment of the different methods in vogue, I was led, in a study of the character of the pathologic structure which existed and of its marked tendencies to union after section as well as its reproductive power, to the adoption of a method by which normal mucous membrane should form behind the cicatricial mass. It was evident that if such a line could be formed the pathologic tissue in front could be severed without fear of union occurring, and the divided portions could be kept separated and their nutrition modified. In performing the operation a long-handled, slightly curved needle armed with a strong aseptic twisted-silk ligature of sufficient length is introduced at the angle of the mouth on the inner surface and carried carefully into the space between the cicatricial mass and the buccinator muscle and the point made to emerge at the position of the last molar tooth of the lower jaw—at which point the posterior border of the cicatricial tissue can usually be felt. The ligature is now seized with the toothed forceps, the needle withdrawn and the ends tied, the ligature lying loosely in the channel thus formed. As the intention is not to divide the mass by the ligature it is permitted to remain without traction, the formation of the canal lined by normal mucous membrane being facilitated by drawing the ligature backward and forward, and thus destroying any adhesions which may form. The introduction of a probe curved so as to easily take the direction of the canal is also of service, and gives the surgeon information as to its condition. When the probe passes readily and smoothly and without provoking bleeding, it may be assumed that the canal is lined by normal mucous membrane.

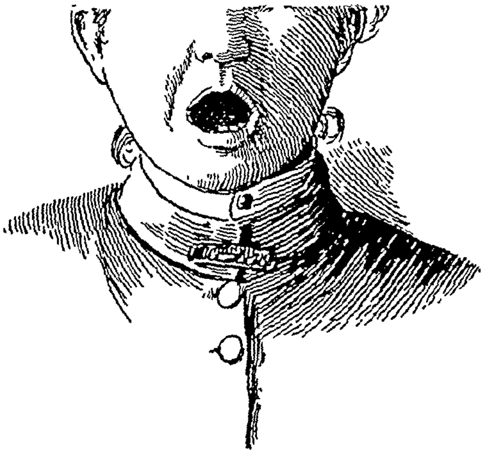

Fig. 1.—Closure due to cicatricial tissue. Operation by introduction of ligature and division of cicatricial tissue.

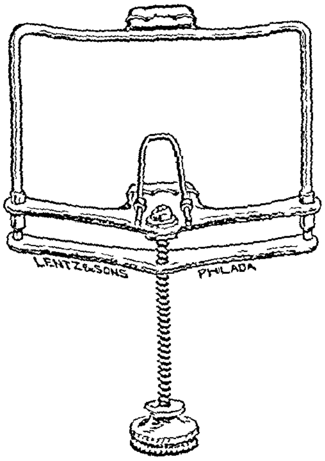

Fig. 2.—Author's gag.

When this condition is established beyond a doubt, in my experience usually at the end of three weeks, a grooved director curved in proper manner, is introduced into the canal and a blunt-pointed bistoury is carried along the groove dividing the tissue as it advances. This being accomplished a gag is placed between the teeth and the mouth forced open to its widest extent. The buccal space is then packed with 5 per cent. iodoform gauze, which is replaced the third day, the cavity being thoroughly cleansed with a disinfecting solution at each dressing. At the expiration of the second or third day the gag should be used, opening the mouth to its widest extent, and each day this should be practiced until there is evidence of the formation of normal membrane lining the buccal spaces, and the patient can without the aid of the gag open the mouth freely, the iodoform packing may be diminished as the reparative process advances. In some instances I have provided patients with a gag and advised its use from time to time, in order that the newly formed membrane may be kept pliable. In a few months, three to four, its use may be dispensed with. My experience with the method above described has demonstrated its value. It overcomes all the objections to the plan which involves the creation of a false joint in front of the cicatrix, and secures as perfect a result as possible.

As the result of jaw-closure which has occurred at an early period of life; dentition is seriously interfered with. In some cases in which I have operated I have found the teeth projecting in all directions, crossing the oral cavity at various angles and forcing the tongue to rest on its edge. In such cases I take advantage of the anesthetic state of the patient at the time of operation to extract all of the teeth and roots which require removal, and thus prepare the alveolar borders for the adaptation of artificial dentures.

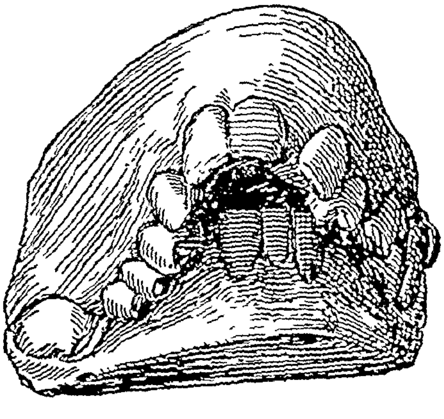

Fig. 3.—Impression of mouth before operation.

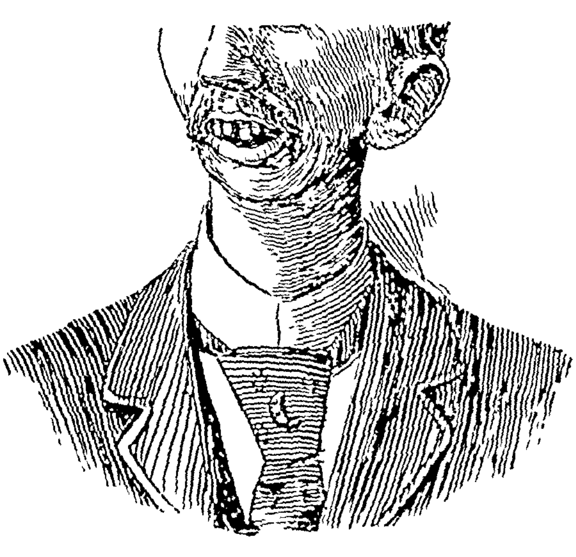

Fig. 4.—Showing condition of non-development of lower jaw.

I referred above to the interference with the development and growth of the bones and soft structures of the face which sometimes occur in cases of jaw-closure. I exhibit a photograph of a case in which this condition occurred to a [illegible] extent [illegible] patient being at the time of operat[illegible], and had suffered from jaw-closure in its severest form for a period of twenty-seven years.

The relief of jaw-closure due to the formation of an osseous bridge is easily accomplished by section of the bridge, a metacarpal saw being introduced and division effected from within outward. If the space between the teeth does not permit introduction of the saw into the oral cavity, section may be made from without inward from the buccal cavity. The disuse to which the temporo-maxillary joint has been subjected by reason of the closure frequently renders the joint rigid and motion painful; the use of the gag for a short time overcomes these conditions. More or less absorption of the divided bony bridge occurs after a time. If the mass is large it may be necessary, in order to overcome deformity, to remove the segments with the chisel or dental saw or burr.

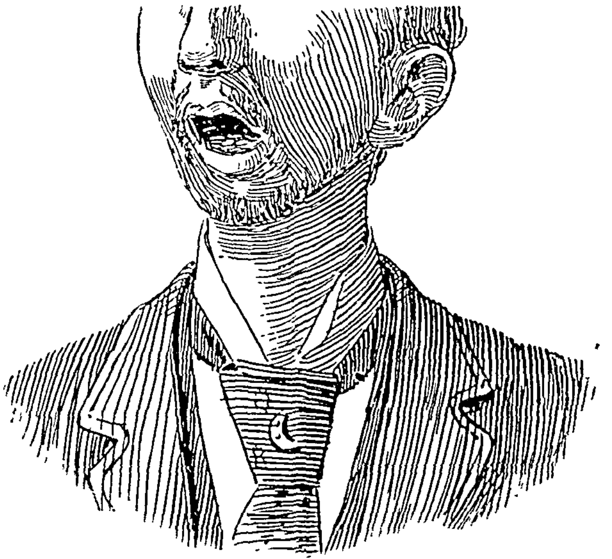

Fig. 5.—One year after operation.

Various methods of operative procedure have been resorted to for the relief of closure due to anchylosis of the temporo-maxillary articulation; these have differed from each other in the selection of the ramus or the condyle as the point at which an effort has been made to establish a false joint. Fibrous anchylosis can be removed by forcibly breaking the adhesions by movements as in the case of any joint.

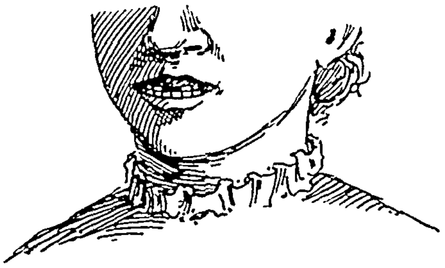

Figure 6.

To Dieffenbach is due the credit of having first practiced division of the ramus of the jaw, and by this operation creating a false joint for the relief of synostosis. Accompanying this method section of the masseter and temporal muscles has been performed. In 1863 Grube, as stated by Professor Gross, formed a false joint by dividing the neck of the bone with a straight chisel introduced through the mouth. Excision of the condyle by external incision in front of the ear, was practiced by Professor Gross in 1874 with excellent results in a case of complete synostosis of the lower jaw on the left side in a girl 7 years of age.

A review of the results obtained by these methods shows that neither accomplished all that was desirable. Section of the ramus was frequently inadequate and as frequently failed entirely by reason of reunion of the bone. Exsection of the condyle, while affording greater motion than section of the ramus, did not secure the establishment of as freely movable a joint as desirable, and moreover was performed by an external incision, which is always an objection by reason of the cicatrix formed on the face.

In order to secure a more freely movable false joint I have practiced excision of the upper half of the ramus, removing both coronoid and condyloid processes by an incision within the mouth. The operation is performed by introducing a tenotome beneath the masseter muscle and forming a opening into which an Adams saw is passed, and dividing the ramus. The upper segment of bone is seized by the lion-jawed forceps and a probe-pointed bistoury is carried through the wound to the position of insertion of the temporal and external pterygoid muscles. The tendons of these muscles are severed and the segment twisted out of its position by the forceps. It may happen that the bone is broken in this effort and the coronoid portion alone removed. When this occurs the chisel is used to remove the remaining portion, including the condyle. In all events enough should be removed to insure ample space for the formation of a large joint, and also prevent, what is not likely to occur, reunion of the bone. The cavity formed is packed with 5 per cent. iodoform gauze for the purpose, not only of separating its surfaces and expanding it, but also for its service in controlling hemorrhage. The position of the inferior dental and the

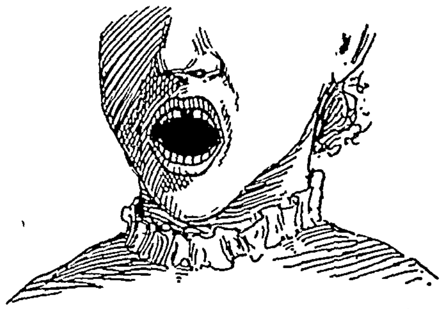

Fig. 7.—Closure due to formation of bridge of bone. Operation by section of bridge by Law. Four years after operation.

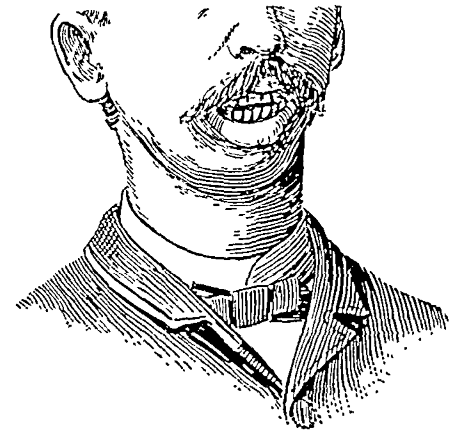

Fig. 8.—Closure due to fracture of the neck of the condyle.

internal maxillary arteries are to be borne in mind, and injury to them avoided. In the event of their being wounded the hemorrhage may be controlled by the gauze packing. Repacking of the cavity should be made on the third day, and then every other day, the cavity being cleansed by the injection of a disinfecting solution. The mouth should be opened by the gag, which should be used daily for the purpose of overcoming the rigidity of the opposite joint and of the muscles, occurring as the result of disuse. At the same time its use facilitates the formation of the false joint. Lateral displacement of the jaw does not follow this method as might probably be expected, as may be seen in the photograph exhibited. In one case it is seen but it will be observed that the deviation existed before the operation and was caused by the inflammatory action which accompanied the necrosis from which the patient had suffered and which produced the anchylosis.

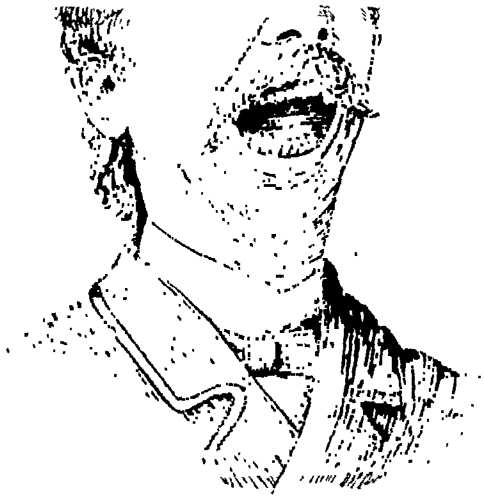

Fig. 9.—Operation by section of ramus and removal of upper segment of bone. Condition 2½ years after operation.

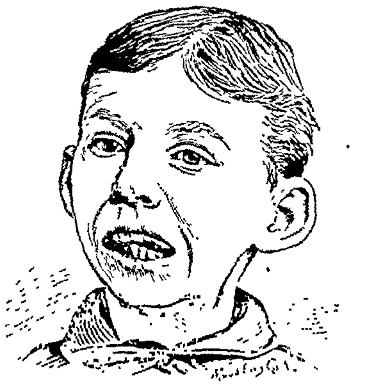

Fig. 10.—Lateral deviation due to necrosis preceding operation.

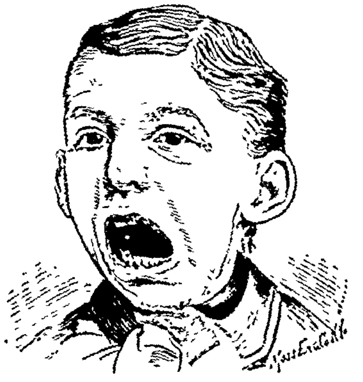

Fig. 11.—Ten months after operation.

The conclusions which I present are:

1. Jaw-closure due to the presence of cicatricial tissue in the buccal spaces can be most efficiently relieved by the formation of a canal lined by normal membrane, by means of a ligature passed behind the cicatricial mass. Reunion of the divided tissue and reformation of the nodular tissue not occurring after division when this canal has been formed.

2. Synostosis of the temporomaxillary articulation, producing jaw-closure, can be best relieved by removal of both coronoid and condyloid processes with the upper portion of the ramus, thus affording ample space for the formation of a freely movable false joint. The operation should be performed through the mouth, thus avoiding disfiguring cicatrices.

DISCUSSION.

Dr. D. MacLean of Detroit—This is a very interesting paper on a specially important subject, particularly on account of its comparative rarity. My experience with these cases has been similar to that of Dr. Mears, and it is difficult to imagine anything more annoying to the patient than this affection. I remember this very well from a case I had some years ago, in which there was synostosis of the jaw occurring after scarlet fever. I believe statistics would show that the disease occurs more often after scarlet fever than after any other disease. In the case I refer to the patient could not move the jaw and I endeavored to relieve the condition by what I thought was an entirely original operation. I dissected off a part of the muscles of the jaw at the angle and resected a V-shaped incision on each side. I kept up passive motion for a long time until a complete false joint was formed on both sides, and I had the satisfaction of securing a useful joint. Dr. Mears has presented a larger view on the subject and I consider his paper a very practical and important one.

Dr. Lewis A. Sayre of New York—I would like to refer to an operation performed for this same condition by Dr. Schmidt of New York. My own son had a case of a similar nature, and by daily prying it open he got a useful joint. Schmidt was one of the first to operate this way, and he did so by dividing the masseter muscles.

Dr. I. N. Quinby of New Jersey—I know that passive motion will sometimes do a great deal, but occasionally a slight division of muscles is first important. We usually see these cases before bony ankylosis takes place and daily movements will enable you to succeed without any more severe operations.

Dr. Montague of Troy—I had a similar case some years ago in a girl 17 years of age, whose jaws were firmly locked and teeth had grown fast. I used wedges to open the jaws and secured a good result.

Dr. R. H. Sayre of New York—The case referred to by my father was one of those where there is some contraction of the soft parts. As Dr. Mears has said, each case must be dealt with on its merits, just as it would be in any other part of the body. Bony ankylosis must be treated on different lines, however, if it is due to cicatricial contraction. The child was in bad shape because the condition had gone on for six years without its parents noticing anything wrong. His playmates laughed at him and teased him and his parents then thought it was worth while to have something done. He ate through a very small hole where some of his teeth had been dislodged. The wedge I used was the one introduced by Dr. Meyer of New York, and consists of two parallel plates. By turning a screw the plates are separated. The plates are lined with lead so as to catch the teeth. A narrow edge was first inserted and later on, when the jaw was further wedged apart, the wedge could be used in another way, and the action of the screw could then be reversed so that wider separation is secured.

Dr. Mears—All of my [illegible] after attempts [illegible] been made by other met[illegible] them had [illegible] for many years, but [illegible] It has be[illegible]manent.

VAGINAL HYSTERECTOMY, A REVIEW OF SIXTY-SIX CONSECUTIVE CASES.

BY CHARLES GILBERT DAVIS, M.D.
CHICAGO.

Whatever adds to the health of woman tends directly to increase the happiness of the human race. On her physical condition hangs the destiny of nations. The truthfulness of this assertion is instinctively recognized by the medical world. Hence, volumes have been written, and a controversial warfare has been waged for centuries in an endeavor to elucidate her diseases and relieve her suffering. So bitter have been these conflicts in regard to the pathology of her ailments and their treatment, that the pelvic cavity may well be called the battle-ground of medical science.

Every generation, every decade, sees new triumphs in the direction of truth. The last quarter of a century has witnessed a revolution in the surgery relating to the pelvic region. While general surgical methods have made a very decided advance, it must be conceded that some of the greatest triumphs have been achieved by improved operative measures employed to relieve many of the various pathologic conditions of the uterus and the adnexa. In the ablation of the uterus, ovaries and tubes much controversy has existed and still continues as to whether the abdominal or vaginal route afford the best results for equal conditions. The discussion, pro and con, has been extensive for the last three years and has augmented to the extent of many volumes. As with all subjects of like nature, there are a few salient points upon which the question hinges. My own observations are made after having witnessed these operations performed by some of the most skilled gynecologists of

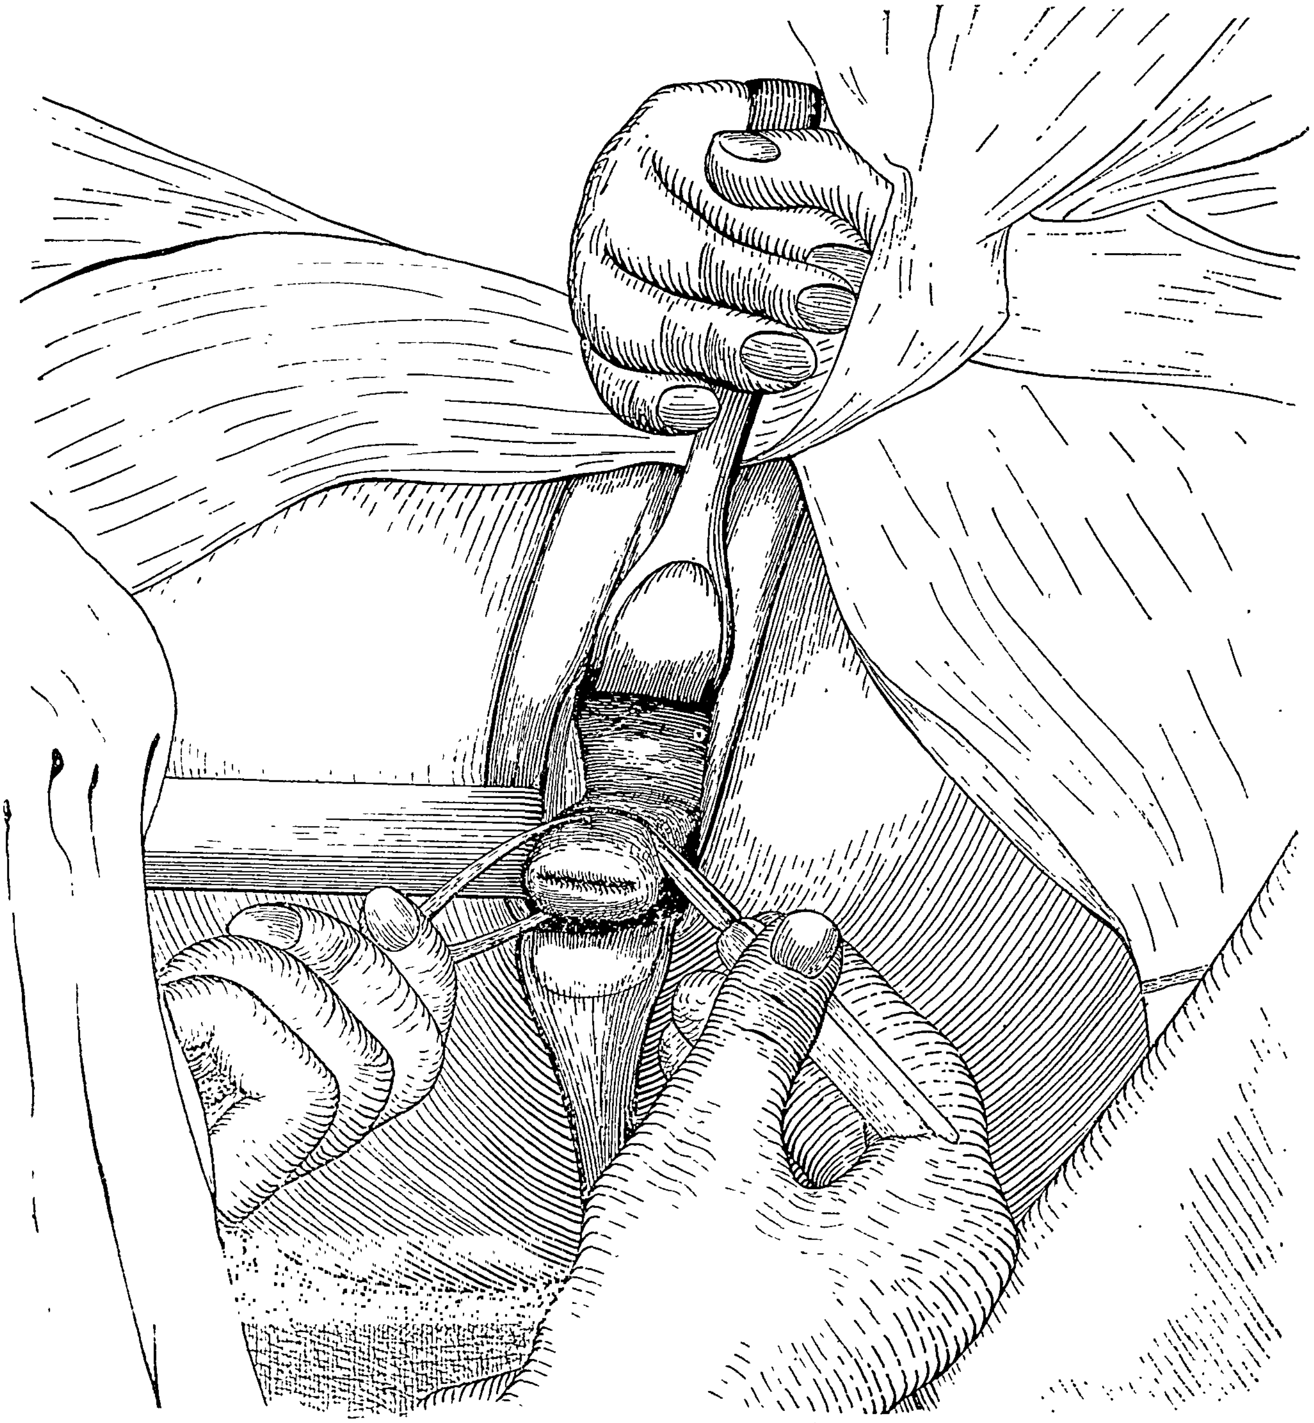

Figure 1.—Beginning of First Stage.

Europe, and then verifying their methods by personal experience. I am satisfied that each of these methods has its sphere of usefulness, and the broad-minded, unprejudiced surgeon will not be slow in making the application. The general of an army who relies at all times and under all circumstances on a single plan of battle, will ultimately meet a most inglorious defeat. The successful man knows that frequently, on the instant, it becomes necessary for him to change his method of operation. Taking all things into consideration, I am satisfied that for most pelvic operations the vaginal route offers by far the best results. With the statistics that we now have, I should regard it as unsurgical and unwise in the extreme to perform any operation on the pelvic viscera abdominally, when there are no logical reasons or indications why the same could not be done by the vaginal method. There are growths, solid and cystic, of the tubes, ovaries and uterus, which we find impossible to remove *per vaginam*, but even here, in many instances, when the uterus has to be removed, I believe the percentage of deaths will be less if we begin or finish the operation through the vagina.

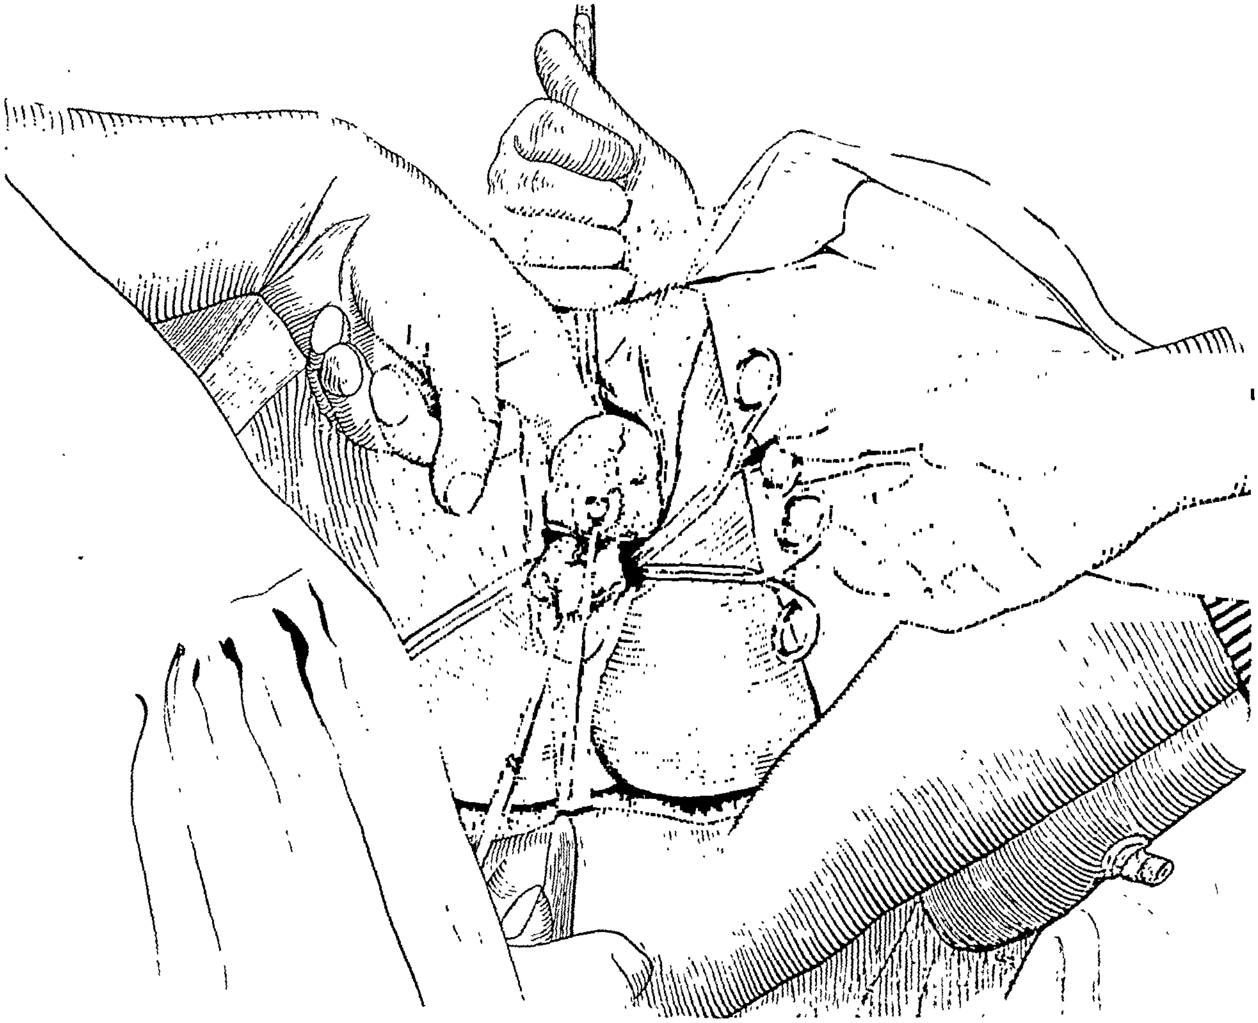

FIGURE 2.—SECOND STAGE.

The question as to the advisability of allowing the uterus to remain when it becomes necessary to remove both ovaries, seems to me to have but little argument in its favor. We know full well that in a majority of instances the inflamed conditions that lead to the necessity of most of these operations have their incipiency in the lining membrane and other tissues of the uterus. If then we stop at the removal of the ovaries we leave behind the real center of disease as the nidus or hatching place of diseased germs, which are liable to prove disastrous in the future. In my opinion, much nonsensical argument has been wasted on this subject. The uterus is simply serviceable in the process of child-bearing. After the ovarian ablation, its usefulness as an organ terminates and it becomes a superfluous and foreign body. I have no sympathy for the sentimentality that weeps over the removal of a permanently diseased uterus. It is far better to make these operations thorough, speedy and complete, than to remove a portion and leave the remainder to cause years of suffering or perhaps necessitate the ordeal of another operation.

I have never removed a uterus for which I felt regret. I have allowed several to remain that I am sure ought to have been removed. I have never known vaginal hysterectomy to be followed by hernia. The vaginal vault seems as strong or stronger than when occupied by the weighty and diseased organ. The sexual function in the mature woman is certainly not immediately diminished. I know of several instances where the removal of the diseased organ has caused an augmentation of the sexual sensibility. As a rule it is therefore safe to say, when we have to remove the ovaries, remove also the uterus, and do it *per vaginam*. The operation may be divided into three stages: 1, The cervix is encircled by an incision and the entire organ is denuded anteriorly and posteriorly, as far as practicable; 2, the uterine arteries are clamped and the uterus is enucleated, or if that is [illegible] removed by morcellation; 3, the ovarian arteries are secured and the uterus together with tubes and ovaries is cut away. The technique of the operation I have described in my article in the Journal of Feb. 8, 1896, where I reported the first twenty-two cases of this series. After observing the German method of operating with ligatures and then witnessing the operation with clamps by Péan, I have not hesitated to adopt the latter method and have never deviated from it.

In my sixty-six cases I have never had occasion to tie a single ligature. Only once has hemorrhage followed the removal of the clamps at the expiration of forty-eight hours. This was from the right uterine artery, and was easily clasped by a clamp which was allowed to remain on forty-eight hours longer. In another case hemorrhage occurred during a dressing on the eighth day, caused probably by too great distension of the vagina with speculum by the nurse. It was not severe and yielded to hot douches. In another case an intestinal fistula manifested itself on the ninth day. This continued for about six weeks and then healed spontaneously. I am satisfied that many accidents of hernia, fistula, secondary hemorrhage, etc., are caused by unnecessary distension of the vaginal walls with dressings. Now, after the removal of the clamps, I never allow a speculum to be inserted until the wound is entirely healed. The cavity is douched once daily, taking care not to allow the fluid to enter the abdominal cavity, and the mouth of the vagina is distended lightly with two fingers and the parts dusted with powdered iodoform, and a small strip of gauze inserted to the depth of two inches. The external genitalia are again dusted with the powdered iodoform and a strip of gauze folded over the parts. A T bandage is adjusted and the dressing is complete. An early evacuation of the bowels expedites the progress of the case. This is usually done by an enema the day following the removal of the forceps. Menstrual storms are certainly modified by an early and prolonged administration of ovarian extract. The patient usually makes rapid recovery. There certainly is no other capital operation known for women to which we may so conscientiously and truthfully after our treatment apply the term "cure." There is not a

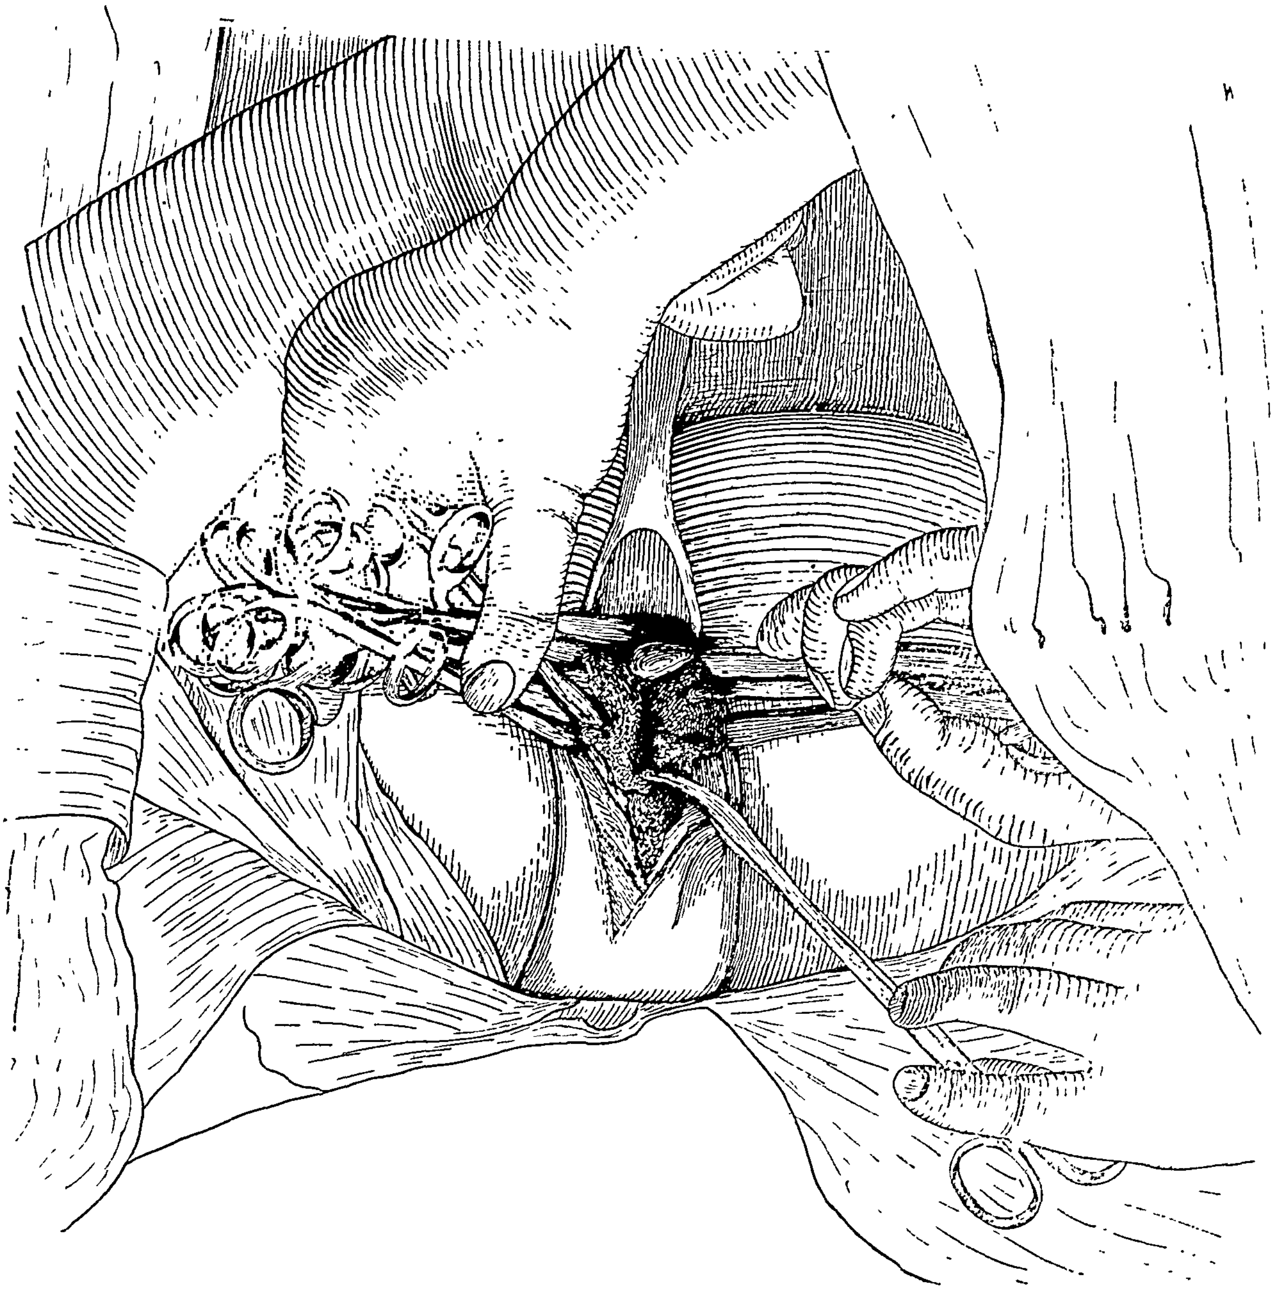

Figure 3.—Operation Complete.

day or a week that by letter or conversation I do not hear expressions of gratitude for complete relief from suffering following the operation.

How often we all have been chagrined and disappointed by the opposite expressions that so frequently come to us after having done our best to relieve the patient by removing a tube, an ovary, or both, through the abdominal route. In many of these cases the removal of diseased structures was not complete and disease still lingered. If I should formulate the rules indicating the operation of vaginal hysterectomy, they would be somewhat as follows:

1. In all cases of malignant uterus where the disease has not advanced too far in the pelvic walls.
2. In maturely developed women where we determine to remove both ovaries or tubes.
3. In removal of one ovary when also the uterus shows evidence of long standing inflammatory action.
4. In all cases nearing the menopause suffering from chronic painful displacement.
5. In all cases of fibroid not to exceed the size of a child's head and involving seriouly the integrity of the uterine walls.
6. In double pyosalpinx and in single if uterus is badly diseased.
7. Whenever from any cause, specific or otherwise, the uterus has been chronically diseased, has long resisted other treatment and proved a center of serious reflex symptoms.

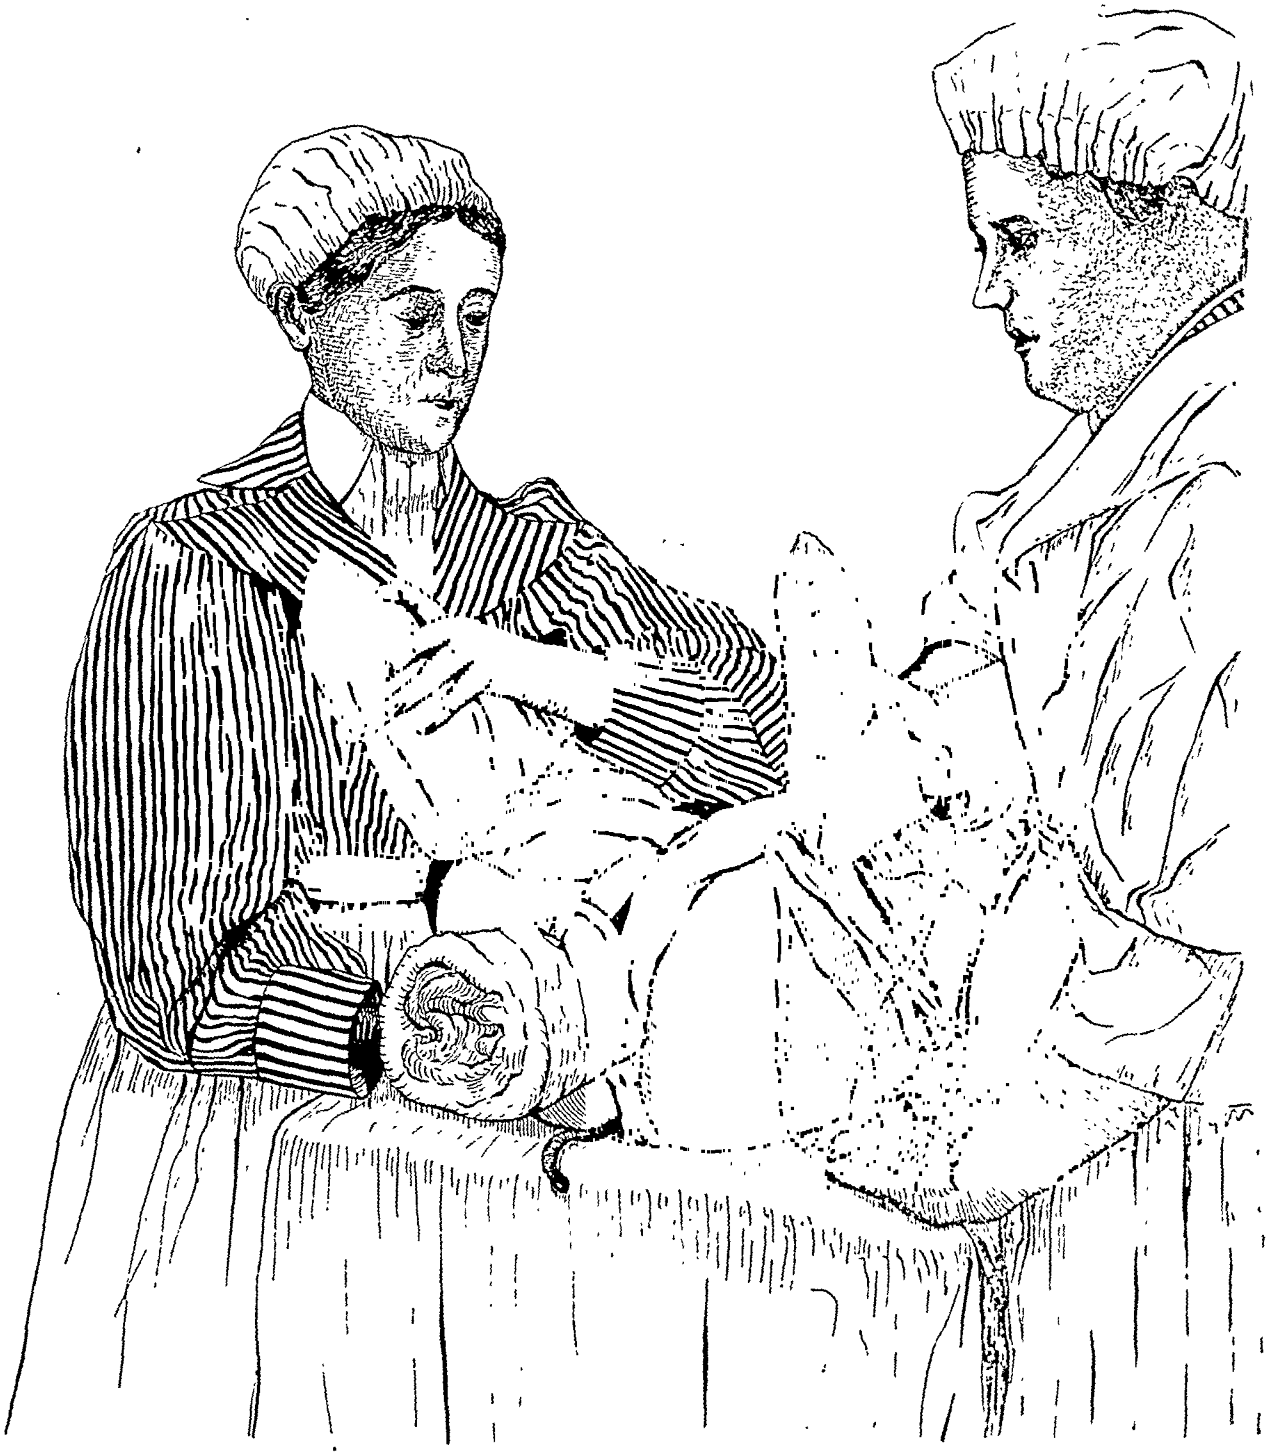

FIGURE 4.—DRESSINGS.

It is not infrequently the case that we begin a vaginal hysterectomy and, owing to adhesions or other causes, are compelled to abandon this method and finish the operation through the abdomen. But it is certainly not detrimental to have made this beginning. In fact, whenever we perform abdominal hysterectomy the most rational procedure is to begin or terminate the operation by clamping the uterine arteries and removing the cervix through the vagina. Twice I have attempted the vaginal operation and been compelled to open the abdomen. In one case the entire pelvic viscera were cemented in a mass of chronic inflammation. I removed a greater portion of the mass with the uterus *per vaginam* and ruptured the bladder, which I subsequently closed by producing occlusion of the vagina. Again, I attempted to remove a myoma the size of a child's head through the vagina. I took away by morcellation the cervix and greater portion of the body of the uterus and clamped the uterine arteries, but the hemorrhage from above became so profuse that I was compelled to finish through the abdomen. I only had to ligate the ovarian arteries, dissect the anterior and posterior flaps and then close the opening into the vagina with catgut sutures. The clamps remained, as usual, forty-eight hours. Neither of these cases is numbered in this series of vaginal hysterectomies. Both recovered. In these sixty-six cases there was but one death.

No alcohol was allowed to any of these patients either before, during or following the operations. My experience during the last twenty years, both with and without alcohol, leads me to believe that when other anesthetics are available surgical cases do far better without its administration. It will be noticed from the table that hypnotic suggestion was used in most of these cases as an aid to the anesthesia of chloroform and ether. I regard suggestion as one of the most powerful fortifiers of the nervous system, and I strongly believe there is no one single thing more calculated to insure the successful termination of a surgical operation than the employment of suggestion as the patient passes into the sleep of anesthesia. It is interesting to note that in the case of the one death occurring in this series, and the other cases of post-operative accident no suggestion was employed. Every surgeon should be thoroughly impressed with the fact that faith, hope, expectancy and belief, when aroused by suggestion, are most powerful aids to insure his patient against collapse and death. With this clearly before him and a determination to observe every minutia and care, he is in the best possible way to operate successfully.

240 Wabash Avenue.

EYE INJURIES PRODUCED BY BLOWS WITHOUT PENETRATION OF OCULAR TISSUES.

BY ALBERT B. HALE, M.D.
CHICAGO, ILL.

I have just been favored with the usual medical triplet of similar cases, this time all being due to our Fourth of July celebration. Our lack of civic control in such matters suggests the necessity of a more direct education of the people in regard to the danger of slow explosives as commonly found in the so-called giant firecracker, for it will be a pity to wait till every family has had personal experience in the matter, before we conclude that promiscuous noise is a necessary token of exuberant patriotism.

My three cases all involved the right eye, two were due to firecrackers thrown from the hand of another person; and while two will end in greatly restricted usefulness, one eye has completely lost its function and may probably have to come out, within the not distant future.

M. H., male, 27 years old, tailor by trade, was sitting quietly at a table in a saloon near an open window, on the evening of July 4, when some public spirited boy threw a large firecracker through the window and on the table. The cracker exploded and the man jumped, put his hand to his eye and exclaimed that he had been hit! The neighbors kindly bathed and bandaged the injury for him, and the next day I was consulted. The powder must have ignited close to his face, for the picture was that of a typical burn of the third degree, where the ocular conjunctiva, *including the epithelial layer on the cornea,* was completely charred. There was some chemosis though no real secretion, but the wound looked as if a cautery (as I have seen its effects when used to destroy lupus of the lid) had passed thoroughly over the surface. The cornea was a remarkable sight; it transparency was lessened, though the iris could still be detected through it, but instead of being a regular, smooth, reflecting surface, it was now rough, covered with most minute protuberances, and looked to me like closely shorn velvet, or something like the cover-glass that has just been pulled from its bed of old Canada balsam. There was not much pain, and a minimum of vision remained. By energetic application of vaselin (cocainized and atropinized), ice, and afterward heat, and by constant watching and continued movement, anything like adhesion between lid and eyeball was prevented, although I ascribe this success rather more to the intactness of the palpebral conjunctiva than to any great influence of treatment. The cornea however, was lost—not that any ulcer formed, but the gradual restoration of epithelium was accompanied by the growth of the most absolutely leucomatous tissue I ever saw, the whole cornea being involved, so that it looked as if a circular piece of very white tissue-paper had by some marvelous means been nicely pasted over the iritic area.

Nothing could be seen through it, either by the doctor or by the patient, and while I have no means of knowing whether or not the other tissues were intact, I judge they were, because soon after the injury vision had to some extent been preserved, while there had been no subsequent symptoms of inflammation. I wanted to tattoo the scar, but the patient failed to keep his appointment, and soon after passed out of my control.

The second case was that of a little girl of seven who, while playing with her neighbors, allowed her curiosity to conquer her caution and was, therefore, too close to a giant firecracker when it was dismissed from the hand of its owner. Here there was a slight laceration of the cheek just below the outer canthus, a decided bruise of the tissue around the orbit and a severe concussion of the whole eyeball. The cornea escaped, but the iris was thoroughly lacerated and the lens substance disturbed, while the hyphema was at first so severe that an exact diagnosis could not be made. When the blood had finally become absorbed, the lens (anterior segment at least) was found to be completely opaque, the iris had been detached at several places from its ciliary insertion, and downward and outward a long thick adhesion was firmly established between iris and capsule exactly in the center of the pupil, so that but a small area of pupil was left above, the remainder of the aperture being occupied by a mass of iris and exudate. Nothing could overcome this adhesion, and with the progress of the cataract vision was gradually reduced to nothing, although light perception was well retained. This patient will soon be operated on, but of course the eye will always be unlike the sound eye and I dare not now promise the restoration of thoroughly good sight.

The third case was that of a boy 13 years old, who let a giant firecracker explode in his fingers while blowing the fuse to see whether it was alight. Here, also, there was no laceration, but intense swelling and some ecchymosis, with severe hemorrhage into the anterior chamber. After the swelling had subsided the iris was found to be torn from its ciliary attachment, there was a large fibrinous band stretching across the aperture caused by the rupture, the pupillary edge of the iris was inseparable from the anterior capsule, while at this spot (nowhere else in the anterior capsule) and to the whole extent of the posterior capsule there is a cataractous formation, which will soon become total, reducing the vision to the barest counting of fingers at one or two feet. Here there must be one operation at least, perhaps several, and though I have great hope of restoring vision by making this an aphakic eye, yet it will always be unlike its fellow and the boy has probably lost some of his commercial usefulness.

The lesson from all this is so obvious that I must restrain my reportorial ardor to sermonize from either a social or scientific point of view. Traumatisms cause about 10 per c [illegible] blir [illegible] ss in Germany and 8 per cent. in Franc [illegible] dents may [illegible] given as due to industrial occupations. Certainly such misfortunes as these can not be classed as industrial and we ought, therefore, to enter in our list of causes of blindness in America, "the Fourth of July."

INTER-COMPLICATIONS OF NEURASTHENIA.

BY JAMES G. KIERNAN, M.D.
FOREIGN ASSOCIATE MEMBER OF THE FRENCH MEDICO-PHYSIOLOGIC ASSOCIATION; FELLOW OF THE CHICAGO ACADEMY OF MEDICINE; PROFESSOR OF FORENSIC PSYCHIATRY, KENT COLLEGE OF LAW.
CHICAGO.

Neurasthenia is an old term applied to a long recognized condition whose relations however have only been cleared of obscurity of late years. The older clinicians described it under the term "nervous adynamia," a peculiar condition of the entire organism most obviously improved and benefited by tonics. The nervous system is the first part visibly affected, the heart the second; the contractile heart fails not from want of blood as in anemia, but more directly as from a shock or some toxic influence. The capillary activity seems impaired, the metabolism and nutrition thereby declined, the contractile power of the heart and blood pressure being much diminished. This condition, which is essentially one of exhaustion, finally fixes itself, whatever be the primary cause, on the central nervous system and finds expression in a nervous instability taking the line of least resistance. It has been claimed that the condition is essentially one of auto-intoxication. It is true that such a condition exists in neurasthenia and is an expression at once of excessive fatigue and its results on the nerve-centers. As Cowles[1] has shown, neurasthenia or pathologic fatigue presents itself in two aspects: 1. In normal fatigue with the discharge of energy the toxic products of exercise are always formed in nervous and muscle tissues. From this and other sources toxic elements may accumulate in the blood and tissues; in pathologic fatigue these contribute to a local or general inanition and auto-intoxication. Visible changes in nerve-cells attending normal fatigue go to support the inference of a molecular and chemic variation in pathologic fatigue manifested as a condition of exhausted or changed nutritional power. These changes bear a direct relation to the etiology and pathology of neurasthenia. Habit, diathesis and idiosyncrasy have an important influence in causing "dispositions to repeat organic processes," both normal and abnormal.

The study of the mental elements in normal and pathologic fatigue shows that the mental symptoms furnish a ready index of the "fatigue": *a*. The emotional tone is either one of well-being or ill-being, and the latter, with mental depression, indicates changes in the "sense of body," or common sensation, due to deficient energy, inanition and auto-intoxication; *b*, special disorders of intellect and will are shown by a neurasthenic weakening of voluntary attention or the mental power of inhibitory control and of memory, etc.

Analysis of normal and pathologic fatigue shows that the mental symptoms of the latter may be readily recognized, that they correspond with the physical events in neurasthenia and that all these phenomena, as far as they go, are in unity with the like conditions of melancholia. (More particularly with acute confusional insanity.[2]) The symptoms are objective and subjective, mainly the latter, which include the mental symptoms. These fall by analysis into four distinct groups relating to: 1, mental depression and a sense of ill-being; 2, diminished power of voluntary attention and mental control; 3, introspection and worry, with attention acting in its attracted form; 4, changes in the "sense of body," irritability and hyperesthesia, languor and anesthesia. Two consequent conditions become prominent and are of the highest clinical importance, morning tire and anesthesia of the sense of fatigue. This summary of symptoms leads Cowles to define neurasthenia (including both the physical and mental elements as expressions of the inanition and auto-intoxication of pathologic fatigue) as a morbid condition of the nervous system with as underlying characteristics, excessive weakness and irritability, or languor with mental depression and weakened attention.

From the inanition and auto-intoxication result the numerous conditions of uncertainty underlying the states which finally become the various obsessions or morbid fears. The cerebral basis of these was many years ago pointed out, as Spitzka remarks,[3] by Meynert, who called attention to the presumptive physiologic rôle of certain arched fibers which are known to unite adjoining as well as distant cortical areas with each other. I should, if asked to point to the chief factor on which the higher powers of the human brain depend, lay stress less on the cortical development as such than on the immense preponderance of the white substance due to the massive associating tracts. Although the projecting tracts are also larger in man than in any other animal, yet so great is the preponderance of the associating mechanism that the elimination of the former would not reduce the white substance of the hemisphere by one-half its bulk. Both projecting and associating fiber masses increase in a nearly geometric progression as we pass from the lower animals to man, but the ratio of progression of the associating fiber masses exceeds that of the projecting tracts. There are certain convolutions which are almost exclusively connected with *fibræ arcuatæ*, that is, with associating tracts, and which enjoy but little direct connection with the body periphery. It is reasonable to believe that such cortical areas so connected play an important rôle as a substratum of the abstractions. Such cortical areas and their subsidiary associating tracts, bound into the still higher unity of the entire hemisphere, constitute the substratum of the metaphysician's *ego*, or may even render an *ego* an impossibility. It is on accurate connection of projection areas with projection areas, and of these with "abstraction" areas that the faculty of logical correlation must depend. The correction of the countless errors made during a lifetime is possible only by an influence analogous to inhibition exercised by the association fasciculi, and the proper aim of every really educational system is to develop this control of the various cortical screens on each other; a correction which with approaching maturity is delegated to the "abstraction" field.

Ordinarily the functions of the "abstraction field" are performed in what, may be termed an automatic manner.[4] Physical exhaustion and other states of constitutional disturbances may destroy this automatism and the individual becomes actively conscious of the will-power needed to control conceptions constantly received from sense impressions. Upon the degree of weakening depends whether simple uncertainty, the morbid analysis of "grubelsucht," or the well marked imperative conception with its transformation into the imperative act result.

---

[3] Alienist and Neurologist, vol. viii.

[4] See article by myself, Alienist and Neurologist, 1890.

It is usually assumed that the *ego* is a centralized entity, when in reality, as Ribot points out:

"The *ego* is a co-ordination. It oscillates between two extreme points, perfect unity and absolute incoordination, else it ceases to be and all the intermediate degrees exemplified without any line of demarcation between normal and abnormal, health and disease; the one trenching upon the other. Wherefore the *ego* in the physiologic sense is the cohesion for a given time of a certain number of clear states of consciousness accompanied by others less clear and by a multitude of physiologic states which though unaccompanied by consciousness are not less but even more effective than the conscious states"

From these conditions result, in addition to the obsessions (imperative conceptions) or morbid fears, the anxious states which express themselves in respiratory or cardiac nervous disturbances, as well as the "helmet" sensation so often mentioned. With these occur the usual evidences of emotional instability which find their expression in the alternations of exaltation and depression that Oddo has called "circular neurasthenia." Like hysteria, the mixed neuropsychic state of neurasthenia may express itself in localized symptoms simulating other neuroses. Some of these of the spinal type have already been pointed out editorially in the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, Vol. XXVIII. One case which came under my observation was said to present even the eye symptoms of locomotor ataxia. The case proved to be one of neurasthenia with predominating spinal symptoms and with certain eye disorders correctable by glasses. Not merely in the spinal cord or in the brain is the line of least resistance in neurasthenia to be found. Very frequently the condition effects the medulla and produces secondary visceral symptoms.

Aside from these, temporary conditions of lithemia, oxaluria and glycosuria are produced, as has been shown by L. C. Gray of New York, Vigoroux and others. Nearly always there is present in neurasthenics an hydro-adipsia, at times amounting almost to a hydrophobia. In all the temporary conditions just described this hydro-adipsia appears, which adds to the difficulties of the treatment of the original state as well as of the complications resulting from these states and the states themselves. Balneotherapy was an old and in many instances beneficial prescription for these states. It however necessitated certain accessories which were injurious to the hyperesthetic nervous system of the neurasthenic, and which to a certain extent tended to undo whatever beneficial effect the balneotherapy might have on the hydro-adipsia. As a large number of cases were best treated by a modified system of rest cure which implied a certain amount of intellectual stimulus to train the will against the already formed or imminent obsessions or morbid fears or emotional instabilities, carrying out of measures against hydro-adipsia is somewhat of a problem. In many instances the addition of lime water to the milk, which forms of necessity so large a portion of the diet of neurasthenics, will introduce sufficient water to combat the effects of the hydro-adipsia. This however does not combat a metabolic instability evident in the lithemia, oxaluria and glycosuria. Among the agents which I have found peculiarly valuable in the treatment of these states and the general condition of neurasthenia has been the ozonate lithia water. This positively creates a thirst hitherto deficient in the patient as a rule; he complains (a complaint hitherto absent) that the water does not seem to satisfy his thirst. Hitherto the thirst itself has been absent and in this case appetite seems to grow by what it feeds on. The water exercises a peculiarly beneficial influence on the helmet-like sensation, on the dull pain complained of at the nape of the neck as well as that in the lumbar region. The water is taken with peculiar avidity just before resting after massage. It seems to exert also not immediately, but after some days, a beneficial influence on the gastro-intestinal manifestations of neurasthenia. Aided by an occasional mercurial it corrects the annoying intestinal atony which is so often present even after evidences of improvement in the general neurasthenic state.

As to dietetics of these complications, nothing need be added to what I have elswhere stated.[5] Each individual case will require special analysis, as Bremer of St. Louis has most forcibly shown. The condition can not be treated purely as an auto-intoxication since, as C. H. Hughes of St. Louis[6] points out, the auto-intoxication often is an expression of the nerve exhaustion and aggravates this; hence both the auto-intoxication, its results and its cause need treatment.

In dealing with the morbid fears, ridicule is most injudicious, since this tends to make the patient reticent and thereby weakens an already feeble co-ordination. Ridicule will not introduce a healthy conception checking these fears, but will increase the patient's morbid distrust of himself and thereby increase the general pathologic fatigue. The same is true of medical examinations which lay undue stress on certain manifestations of the general disorder. The evil effects of laying undue stress on the utero-ovarian manifestation has been emphatically pointed out by Goodell, but the same evil effects are observed in cases treated by ophthalmologists, who recognize only the eye side; by rhinologists who recognize only the "catarrh" side; by dyspepsia specialists, who recognize only the gastric side; or by spermatorrhea specialists and by others who concentrate the patient's attention entirely on one symptom, thereby affording him new material for morbid anxieties. I have not dwelt on the use of either faradic, galvanic, or static electricity, because each of these has its indications in the particular case and, like all other procedures, is apt to be abused when used on general principles. The neurasthenic must be treated as a patient, not as a disease label, bearing in mind that his condition is due to pathologic fatigue and its consequences.

IS IT ETHICAL FOR MEDICAL MEN TO PATENT MEDICAL INVENTIONS?

Presented in the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty eighth Annual Meeting of the American Medical Association, held at Philadelphia, Pa, June 1-4, 1897

BY F. E. STEWART, M.D., PH.G.

DETROIT, MICH.

I use the word patent in the sense commonly accepted by the medical profession, viz, "restrained from general use," and, by medical men I mean physicians, surgeons and apothecaries, for they are all practicing medical arts.

---

[5] Therapeutic Gazette, April 15 1897

[6] Alienist and Neurologist, Vol xviii

In his primitive state man lived on the fruits of the field without being obliged to till the soil, but as people multiplied on the face of the earth, agriculture was one of the first arts which man practiced. The inventor of the plow may have named it, or the name may have been given it by some one else. At any rate, the name plough was given by somebody who coined the title for that purpose, and it was afterward modified to plow. Here we have an original invention of the purest kind, and a coined word given to it as a title. I can not conceive any reason why the inventor of the plow should have desired to prevent others from using it, but, for the sake of argument, suppose the inventor of the plow had concluded to prevent others from using the trunk of a tree for scraping up the soil. Theoretically, his every neighbor was as strong as he, and combined they were stronger, and therefore he could not have maintained the exclusive use of the plow if he had so desired. It is evident therefore that the inventor does not possess a natural right to the exclusive use of his invention. In other words, he has no property in it *per se*. How did it ever come to pass that inventors acquired property rights in their inventions? After a time improvements were made in the plow, and it became more complicated and required a greater amount of skill for its construction. Certain men made better plows than others, and their neighbors desiring to possess the improved article, and recognizing the peculiar ability of some men to make plows, commenced to employ them for that purpose, exchanging commodities of their own for plows. Every improvement in the plow devised by one man was carefully concealed from others engaged in the manufacture of plows, so as to obtain commercial supremacy thereby. As the world continued to grow and competition became more general, inventors of those improvements now commenced to quarrel with each other, each one saying that no one had a right to copy their inventions. What applied to the art of manufacturing plows applied also to every other art, as soon as it was invented. The government finally intervened to stop the quarrel, and passed laws for that purpose. These laws are known as patent and copyright laws. They are designed to promote progress in science and the useful arts. They do so by granting to authors and inventors for limited times the exclusive use of their respective writings and discoveries. They recognize the value of authors and inventors to the community and encourage authorship and invention. They are designed to secure the publication of knowledge and not to lock up knowledge to trade secrecy, or to protect inventors in the exclusive use of the knowledge of their inventions. The moment an invention is patented full knowledge of it is divulged, as the application for patent must contain full knowledge of the invention in language sufficiently plain for any one skilled in the art to duplicate the invention. A copyright on a book, while restraining the writing itself from general use for a limited time, does not in any way restrain the use of the *knowledge* contained in the book from the public. While under the copyright and patent the book and the invention are restrained from general use for limited times, both become free to the use of the public after the right has returned to the public who gave it. Commerce as well as science is thus benefited by these laws.

The medical profession has for many years past permitted its members to copyright their books. Is there any reason why they should refuse to sanction the patent which restrains a medical invention from general use for a limited time in exchange for the publication of exact knowledge of the invention for the benefit of science?

The arguments which have been used against medical men patenting medical inventions are as follows:

1. Every substance used for the treatment of the sick should be left free from all control by secret processes and patents, so that they may be manufactured and dealt in at the least expense to the consumer, *i. e.*, the sick; and be open to free investigation by all who desire knowledge concerning them.

2. For the purpose of creating a demand as articles of commerce medicines must be advertised, and the advertisements being worded for the purpose of selling goods creates a fictitious demand for the products advertised, thus displacing older and well-tried drugs by medical novelties.

3. The only object in patenting a medical invention is to utilize it for money-making purposes, which can only be done successfully by the adoption of trade methods. Physicians who patent medical inventions or offer medicines for sale enter the domain of trade thereby, and cease to be professional men. The liberal professions, viz., theology, law and medicine, deal exclusively in advice, not in material substances. This differentiates them from the trades, and if medicine is to remain one of the liberal professions it must not adopt trade methods.

4. The medical inventor who has a material substance for sale will unconsciously use his best endeavor to promote the sale of his goods, rather than make it his chief object to benefit his patients who may purchase his goods. This would change the nature of medical practice from a beneficent one to a distinctly commercial one, and while all legitimate business is beneficent, in one sense of the term, the physician's vocation is pecularly philanthropic, having as its chief end the relief of human suffering, not the acquisition of money.

The physician who copyrights his books is not tempted thereby to do anything contrary to beneficent and professional liberality because it would not be profitable for him to do so. Does not the same thing apply to the patenting of surgical instruments? What object could a surgeon have in misrepresenting his instrument? Could there be a fictitious demand created for an instrument by advertising it? Could he displace the use of better instruments by publishing extravagant claims concerning it? If so, it would not be public policy for the profession to allow a surgeon to patent has instruments.

How about the pharmacist? Should he be allowed to patent medical inventions? It seems to me that the same arguments apply to him that apply to the physician and surgeon. If he is allowed to patent medical products he is at once tempted to resort to misrepresentation for the purpose of creating a demand for them, that he may displace older and tried methods of treatment by therapeutic novelties which may, or may not, be improvements on what are already known. Moreover his vocation is that of preparing medicine for therapeutic use, and he has no right whatsoever to practice therapy, unless he is educated and trained for that purpose.

I admit that there is a trade element in pharmacy which does not pertain to the practice of therapy.

The physician deals in advice only, while the apothecary has material substances for sale. The apothecary is obliged to carry a large stock of goods which he deals in as merchandise, and is obliged to serve the public at large as well as the medical profession. To do business successfully he must adopt some business methods; but there are some business methods which may be adopted with propriety by the dry goods merchant that can have no place in pharmacal practice. On account of this trade element in the practice of pharmacy, and the necessity of investing capital which must be protected in the conduct of his business, I believe that the pharmacist should be permitted to patent, not medical products, but medical processes, apparatus and machinery employed to prepare medicine. But secret processes and methods are a hindrance to progress in the knowledge of pharmacy, and an open door to fraud. There may be trade secrets the divulging of which for the benefit of competitors might cause serious injury to perfectly legitimate trade interests. If a commission of competent medical men, removed entirely from trade, and outside of politics, could be appointed to act as a board of control in this connection, so that the interests of science, the professions and the public, could be protected from all danger of fraud, I can see no reason why such trade secrets should not be permitted to continue for limited times. But, in the long run, they must be published for the benefit of medical science, and the arts of pharmacy and therapy, which are dependent upon this publication for progress.

There is a business known as the "patent" or "proprietary" medicine business which stands right in the way of the proper understanding of the patent and trade-mark laws by the physicians and pharmacists. It should be described as the secret nostrum business, for the products which it has for sale are rarely patented, but are monopolised by secrecy of composition, secret processes, or in other ways in which secrecy forms a part. While secrecy is the rule there are other medicines which belong to the same class, for while their nature may be known, the advertisements concerning them are purposely worded to create a fictitious demand far in excess of their merits. The name "patent" for a secret medicine is a misnomer, for, as the *Scientific American* says, a thing patented is a thing divulged;" and the name "proprietary" is a misnomer also, for, as already shown, there are no property rights in a medicine to be had, without patenting it. This business is characterized by misleading names, misleading methods, and an abuse of the trade-mark in which the only titles by which the compounds are known are made the subject of monopoly.

According to all authorities on trade-marks which I have consulted, the commonly accepted name of an article can not be a trade-mark. Everything must have a name given it, and whatever name is given a thing becomes its proper appellation. Referring to the origin of the trade-mark, Browne, in his comprehensive work on the subject, says, "trade-marks had their origin in a general ignorance of reading the combinations of cabalistic characters that we call writing. A written certificate of the genuineness of any article of merchandise could not be understood by the nomadic peoples who desired to barter natural products for something made by the hands of skilled artisans. A simple emblem, as a crescent, a sun, a star, an animal, or other object copied from nature or devised by fancy, when once associated with a particular class of goods, or the handicraft of a certain man, would readily be understood."

The only possible use for which a trade-mark can be legally put is to indicate ownership or origin. A trade-mark and a patent have nothing in common, and yet it is the object of the nostrum trade to make it appear that the trade-mark creates a monopoly. This is done in the following manner: A fanciful name is devised and applied as a title to a medicine, and the title is registered in the Patent Office as a trade-mark. Then the nostrum manufacturer says, "you can not manufacture my nostrum, for I have a secret process which prevents you from duplicating it, and even if you can find out how I make my nostrum, you can not deal in it under the title which I have registered as a trade-mark."

The absurdity of this claim will become perfectly apparent to anyone who will take the trouble to study the meaning of a trade-mark. A trade-mark is a thing of natural right and common law. The government has no power to grant anyone the use of a trade-mark. Registering a title as a trade-mark does not make it such. A title can not be a trade-mark and a title at the same time. The name of a thing belongs to the thing itself, not to the one who names it. Because the name was coined or invented makes no difference. Every word in the language was invented or coined at some time or other. No man has a right to monopolize part of the common language even though he may add a contribution to it by coining a name to represent a thing or an idea. The trade-mark system, so-called, is not a system of trade-marking at all, but an attempt to defeat the patent law by a misuse of law, and to obtain privileges of monopoly which that law will not grant, and which the public would seriously injure itself by granting. It is a system of secrecy and unlimited monopoly, and a cloak to fraud and deceit.

Taking all these facts into consideration, it is apparent that the patent, trade-mark and copyright laws should be so interpreted and administered by the court that they will secure the greatest good to the greatest number, and aid in attaining the end of government, viz., "moral, intellectual and physical perfection." It is not the object of these laws to create odious monopolies, to throw a mantle of protection over fraud, to enable quacks and charlatans to encroach on the domain of legitimate medical and pharmacal practice, or to support an advertising business designed to mislead the public in regard to the nature and value of medicines as curative agents. The morals of the community are injured by some of this advertising, intellectual vigor is impaired by the use of many things advertised, and physical as well as moral degradation frequently results. Crime is often inculcated—even the crime of murder, that the nostrum manufacturer may profit thereby. Cures for uncurable diseases are promised and guaranteed. Every scheme that human and devilish ingenuity can devise to wring money from its victim is resorted to which can be employed without actually bringing the advertisers into court. All this wicked quackery parades under the guise of "patent" medicines, and asks the protection of our courts. It is time for the medical and pharmaceutic professions to unite and unmask this monster, and show the public its true nature. And this can be accomplished in no better way than through a study of the object of the laws which the secret nostrum manufacturers are now endeavoring to prostitute for their own advantage, and the teaching of the public what these laws were enacted for, and how they should be applied for the benefit of the country.

I do not wish anyone to take what I have said as a reflection on individuals or concerns. The secret nostrum business in some of its phases has assiduously found its way into the medical arts, and physicians, pharmacists, and manufacturing houses seem to have forgotten to a certain extent the obligations which they owe to the public. Medicine, in all its departments, must be practiced in accord with scientific and professional requirement or it will sink to the level of a commercial business. The end of medical practice is service to suffering humanity, not the acquisition of money. Money making is a necessary part of the practice of medical arts, not however, its chief object. This fact must be kept in view always. Once lost sight of, and trade competition substituted for competion in serving the interests of the sick, medical and pharmacal practice will become an ignoble scrabble for wealth, in which the sick become victims of avarice and greed. Better set free a pack of ravening wolves in a community than to change the end of medical practice to a commercial one, for physicians and pharmacists would soon degenerate into quacks and charlatans and take shameful advantage of the community for gain.

DISCUSSION.

Dr. J. V. Shoemaker—I have been recently almost a victim of a trade-mark firm who brought suit against me to the extent of a hundred thousand dollars, if I did not retract certain statements with regard to two words which were joined together in my text-book on "Therapeutics and Materia Medica." The words had been well known to the profession for years, but they had appropriated them as a trade-mark and denied every one else the right to use them. One of the greatest evils which the medical profession is suffering from is the use of coined words in medicine. I say this after corresponding with two law firms in Western cities, and I was obliged to get legal advice to prevent them from interfering with the sale of my book. They objected to the use of this compound word because they claimed that they had a secret method of combining these two substances, which no doctor or other pharmacist could use. This shows the evil effects of doctors using drugs which are not official.

In the last few years, during which it has been my privilege to teach materia medica, I have taught the student to prescribe official remedies. I have alluded to this subject merely for the purpose of adjusting the fraternal relations between the druggist and the busy doctor, who should see that every drug used in his practice could be obtained from every pharmacist. They should both unite to prevent the sale of those remedies which wring millions of dollars from the pockets of our patients. At the time I referred to I made a little study of the matter and went to several hospitals, and found that more than half of the drugs were trade-mark preparations. That is to say, that instead of spending one hundred dollars, they were spending four hundred dollars for proprietary medicines which were slowly absorbing the resources of the institution. If I had my way I would not have any remedy used in a hospital, which could not be found in the pharmacopeia, or could not be purchased in every drugstore. The physician who prescribes proprietary remedies is simply driving his patient to self-prescribing. I hope that the time will come when our committee will drive all proprietary medicines from our exhibition rooms.

Dr. Eccles—I may say that the last speaker has not been the only victim. I have been vilified by the trade-mark people, and threatened with prosecution. I have taken the ground that all secret preparations are detrimental to medicine, and the better a preparation it is the greater harm it does to medicine. If every manufacturer had followed the course of one firm in Brooklyn, Dr. E. Squibb, it would have been a splendid thing for medical science, for then everything would have been left open to the profession. As regards patents there are two sides to the question. There should be some reward for these original investigators in order to stimulate invention. As regards antipyrin of Dr. Knorr, it is not a secret preparation and it is well known; it might not have been invented had it not been for the fact of the reward offered by the patent laws. The inventor may labor for years, and spend money in experimenting, and if he succeeds in discovering something useful and valuable, he should have his reward. I think that there should be some way arranged by which he could surrender the patent and the government buy it outright. As it is, some inventors are paid too much.

Dr. Hoff of Pomeroy, Ohio—To illustrate the improvement in the sentiment of the profession toward secret or trade-mark medicines, I may say that, in 1845, when I was a student at Jefferson College, one of the faculty gave permission to a manufacturing firm to exhibit his preparations to the class. The Professor stated that he would not recommend them but the students could use them if they saw fit.

Dr. Koenig—I hope that the time may come when no secret or patent preparations will be allowed to be exhibited at these meetings. I may cite the recent meeting of the Pennsylvania State Medical Society as a precedent that we would do well to follow. The Committee on Entertainment resolved to abandon the usual exhibition and they went to the State Pharmaceutical Society and invited the pharmacists to use the exhibit hall in a display of legitimate pharmacy. The exhibit was a great success. Physicians need to have their attention directed to official preparations as there are a great many preparations in the pharmacopeia which physicians never use.

Prof. Remington—I have much admiration for the devotion of Dr. Stewart, who has been pegging away at this subject for twenty years, and I am glad to see that his work is at last beginning to tell. I only want to say that, if the American Medical Association would only do something on this subject it might do good. The physicians are more to blame than the pharmacists. I was present at a meeting of the Pennsylvania State Medical Society, fifteen years ago, and I was asked to present the "National Pharmacopeia and Formulary." I made some suggestions then which were received enthusiastically by Dr. Howard A. Kelly and others, and the exhibition which Dr. Koenig has referred to is a result and an outgrowth of that discussion at that meeting.

The Committee on Revision, in 1880, refused admission to cosmolin, a proprietary article, but admitted the same product under the name of petrolatum. The result is that it can be bought now at seven or eight cents a pound, although, as a proprietary article the price was fifty cents per ounce. The public really does not know how much money has been saved by this action of the Committee. I approve highly of the interest and co-operation of the general profession in the work of the pharmacist and especially in that of the Committee on Revision.

Dr. Haines—The Medical profession has the reputation of being the most liberal profession on the face of the earth. This came up at Atlanta, where a delegate was refused permission to register because he had applied for a patent; he had not even obtained a patent. The Association set its stamp of disapproval upon the holding of a patent by a physician. It has been said that a man should be rewarded for his labors by giving him a patent, but our fathers demanded nothing of this kind. They contributed everything freely for the sake of science and humanity, and we should emulate their high aim and not stoop to commercialism by holding patents.

Dr. Squibb—I agree with Dr. Stewart in most points, but I think that his final statement conflicts with points that he made earlier in the paper. He gave me the impression, at first, that he believed a physician should patent his inventions and discoveries, but later he reverses this. I do not myself think that anything should be patented by either physician or pharmacist; I am sure that the patient would not be benefited thereby. I may say with regard to the sale of patent medicines, that the medical journals themselves are largely responsible for the existence of this class of remedies. If the journals would cease to distribute their advertisements the sales would fall off 75 per cent. If editors of journals would use their influ*ence to discourage the publication of such testimonials*, it would be of great advantage.

I would like to say something about what Dr. Stewart has done in previous years; I have agreed with him in the main and do not care to discourage his good work any longer.

Dr. F. E. Stewart—With regard to patents, my idea is that the present trade-mark and patent laws, if properly applied and carried out, would do more than anything else to restrain the sale of this class of preparations, and end the patent-medicine business. When I appeared before the Committee on Patents, at Washington, and they agreed with my views and asked if I wanted to modify the law. I said, no, only enforce the law.

The trade-mark proprietary medicine purveyors do not want any analysis of their preparations to appear in the journals or text-books, and threaten prosecution to those who publish this information.

To show their animus toward pharmacists, I may refer to articles which they have had published in the public press, stating that the druggists are unreliable and not to be trusted, and will put up their own drugs, which are inferior, the only reliable product being the proprietary preparations.

REPORT OF THE COMMITTEE ON PHARMACOLOGIC INVESTIGATION.

Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Forty-eighth Annual Meeting of the American Medical Association, at Philadelphia, Pa., June 1-4, 1897.

BY H. H. RUSBY, M.D.

CHAIRMAN.

This committee was appointed in August last, immediately after the naming of the delegates from the American Pharmaceutical Association to attend this meeting, and proceeded at once to arrange for the investigation of several problems, selecting phytolacca, virburnum and strophanthus as the drugs to be studied.

The design was to secure the separation in a pure state from each of these drugs of all those constituents upon which its activity might possibly depend, to ascertain by physiologic examination which of these were the active constituents, to determine the percentage in which they existed naturally in a sample of average good quality and to fix methods for the selection of a drug meeting this requirement. In the case of phytolacca it was desired to determine the differences in composition between the drug in a fresh (that is, undried) condition and after drying and how, if at all, such difference affected its medicinal properties. In the case of viburnum it was desired to ascertain how, if at all, the v. prunifolium and v. opulus of the pharmacopeia differed and whether the other viburnum barks found in the market under these names shared their properties and to how great an extent. In the case of strophanthus it was desired especially to determine whether the use of the so-called "brown seeds" is justifiable, and in a general way to fix the comparative value of the other varieties on the market.

The results of the committee's efforts on this occasion illustrates the importance of this method of organizing such work considerably in advance of the time when the reports are to be presented. It has been found, in spite of the utmost diligence, that the year has not afforded sufficient time for the completion of more than one of these problems. The determination of the composition of poke-root has progressed satisfactorily, but the examination of the constituents has not yet been made. It is believed that the active constituent of viburnum has been discovered, but its isolation has presented remarkable difficulties and a sufficient supply is only just now being prepared for study. The complete report on these two drugs will therefore of necessity be postponed until another year. The results of the study of strophanthus are indicated in the program for this meeting. Prof. Smith Ely Jelliffe of the New York College of Pharmacy has made a study of the seeds in their crude condition. Dr. Alfred L. R. Dohme has made a thorough chemic study of the different seeds and is able to draw conclusions as to their comparative value based on such examination. Dr. R. W. Wilcox of the New York Post-Graduate School of Medicine has studied clinically the preparations put in his hands by Dr. Dohme, and has thus completed the series of studies, so that the Revision Committee of the United States Pharmacopeia will now be able to define and describe this important drug on an intelligent basis.

SURGERY ONE HUNDRED YEARS AGO.

AN HISTORICAL STUDY

BY DR. GEORGE FISCHER.

DEDICATED TO THE GERMAN SURGICAL ASSOCIATION.

TRANSLATED FOR THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION BY CARL H. VON KLEIN, A.M., M.D.

CHAPTER XII.—FRENCH AND ENGLISH WAR SURGERY.

(*Continued from page 542.*)

In order to have as much *fresh air* as possible, the minister of war of the republic instructed the commissioner of health to provide the necessary means. He decided upon the following: "Upon his admission every patient was to have his hands and feet washed; in the wards which the attendants were to sweep twice a day, there must be basins with pure water; facilities for bathing must be provided in every stationary hospital; twice a year the wool in the mattresses must be renovated and the wards must be whitewashed at least once a year, and the bedsteads and tables be frequently washed. For every ward a certain number of beds was allowed, and this number was never to be exceeded; they stood from two to two and a half feet apart and never in more than two rows. The basins were oiled, outside and inside, and after use were immediately cleaned. In order to admit fresh air into the wards doors and windows were opened, the latter being provided with rollers and ventilators. The heating was done by fireplaces or stoves, with funnel-shaped draft-pipes. More than 15 to 16 degrees of heat was not permitted in the rooms and when the weather was very warm the floors were sprinkled and fresh green leaves strewn about. All fumigation was forbidden as it only concealed bad air without creating fresh air. Neither stagnant water, manure heaps nor rubbish were tolerated in the neighborhood of the hospital.

Gradually the system of the *transportation* of the wounded in the French army developed. In the war of 1758-59, even on the second and third days after the battle, Colombier saw the wounded lying on the field half dead, naked and trod upon, and indeed, this was on the side of the victorious army, and it must have been much worse on the side of the enemy. The ambulance wagons were very poor; the sick lay close together upon the straw without sufficient covering. Colombier, therefore, proposed to construct wagons in which the wounded should be suspended in a kind of bed, in order to protect them from too violent jolting. In each wagon, which should be fourteen feet long and five feet wide and drawn by four horses, were four hanging berths with straw-sacks and covers for four patients, besides two seats for the surgeon and attendant. It could be entered from the front as well as from the rear. For the sake of lightness, the wagon was made of wicker and covered with painted linen. The cover could be opened and had two windows for the admission of air. Four-wheeled wagons were first introduced for transport in the year 1788, one wagon being allowed to about a thousand soldiers. These were so cumbrous and unwieldy, that the soldiers preferred to be carried from battle on guns, boards, [illegible] desired that every wounded soldier who had been carried to the depot on the day of battle should bring with him a bulletin (une note), concerning his wound and bandage, which when there was a sufficient surgical force could very well be carried out (l. c. ii, p. 314); another idea which by no means belongs to our time as one might suppose. It is well known that in the beginning of the campaign of 1866, in the Prussian army, diagnosis tablets of parchment were distributed and pinned upon the breast of the wounded soldier; an arrangement which later the Berlin Conference acknowledged to be very much to the purpose. This military physician also required that a sufficient force of men be at hand to transport the wounded, so that they could be operated upon and bandaged as soon as possible; for he had already had the experience that a much greater proportion of those who were operated upon on the battle field recovered, than of those who were treated two or three days later when swelling and fever had set in. Every transport train was accompanied by a number of surgeons, attendants and a detachment for escort. The republic stipulated those injuries which transportation would aggravate, and forbade the conveyance of all wounded about the head, with a broken limb, with a large blood vessel ruptured or with a badly inflamed wound. On the decampment of the army no one could be left behind in the field hospital. Transportation by water was given the preference. During Napoleon's wars, many improvements were made by Percy, the chief of the medical department. He introduced new ambulances (chairs de chirurgie), which were drawn by four horses, accompanied by surgeons and attendants, and contained bandaging apparatus and litters. He also organized a corps of litter bearers to carry the wounded out of the battle to the place of bandaging, and to serve as attendants on the ambulances. They were armed with lances, which served at the same time in carrying the wounded, for with two lances, pedestals and canvas which the litter bearers carried in their haversacks, a litter could readily be constructed. Larrey introduced a new wagon which, d by surgeons on horseback, moved with great pidity under the fire of the enemy and picked up e wounded. In Egypt he transported the wounded in baskets suspended on each side of a camel.

Among the *French military* physicians of the last century were some excellent practitioners, most of them members of the Collège de St. Côme in Paris. There was scarcely a prominent surgeon who had not served a long time in the army; among them were J. L. Petit, Maréchal, La Peyronie, Le Dran, Arnaud, Louis, Morand, Garengeot, La Faye, Sabatier, Pelletan and others. *Ravaton*, chirurgien-major in Landau, was an eminent military surgeon who, after an experience of thirty-six years in the wars, wrote a "Chirurgie d'armée ou traité des plaies d'armes à feu," 1750 (2d Ed. 1768), the most exhaustive work of his time on gun-shot wounds. This work, in which were given many conservative cures of gun-shot fractures, and in which amputation was recommended above the malleolus with two flaps instead of below the knee-joint, created a great sensation in the Académie de Chirurgie. It excited such violent debates, that it was proposed by several that the book be burned in the court yard of the academy as unworthy of French. surgery. However, this proposition appeared too intolerable and was rejected by the president, Le Martinière. As a medical writer on military subjects *Colombier*, who had participated in the wars in Germany, became known by his five volume "Code de Médecine Militaire" (1772), a counterpart of Pringle's Observations. All that pertained to the well or the sick soldier, in the field or in the garrison, and to hospitals, army diseases, duties of the military physician, etc., were exhaustively treated. To the military surgeons of a later time belonged *Bagieu* and *Trecourt*, who like Ravaton, approved of amputation above the joints and pointed out the evil consequences of too long continued strict diet in surgical diseases. Then came the quarrelsome, impatient *Lombard* of Strassburg, who, in 1792, as chirurgien en chef, accompanied the army of the Rhine to the field. His service consisted in showing the necessity of purgatives in various surgical diseases, and in contending against the hasty and frequent bleedings practiced by French surgeons in injuries. In the "Remarques sur les lésions de la tête" (1796), he protested against the abuse of trepanning. At the close of the century French military surgery reached its highest development under Napoleon, who through his new plan of war, made new demands upon surgery and had the good fortune to be supported by the great talents of a Percy and a Larrey. Their personal example as well as the high respect and dignity which Napoleon accorded to them awakened among the military physicians an extraordinary zeal. Baron *Percy* († 1825), inspector-general of the French military medical system, had participated in the wars in Germany and Spain, and had distinguished himself by his operative skill and had eminent executive ability. Besides his improvements in methods of transportation, during a battle, he visited on horseback all the surgeons, and had them carry their instruments in cases from their shoulder belts, and lint and bandage material in their pistol belts, so that they could render assistance as quickly as possible. Later, he invented light wagons for conveyance. His prize essays on the use and form of scissors and on the extraction of foreign bodies from shot wounds, have been already mentioned. In his "Pyrotechnie chir. pratique" (1794), he taught the use of the cautery, especially in cases of hospital gangrene, and recommended moxa in cases of inflammation of the hip and knee-joints and vertebræ. He also advocated resection of the joints. *P. F. Moreau* deserves the highest credit for the introduction of this operation ("Observations pratiq. relat. à la résection des articul. affect. de carie," 1803). The Frenchman, *Boy*, appears to have been entirely forgotten; under the republic he was chief surgeon of the army of the Rhine, and also made a reputation for himself as an orator and poet, but died young—a martyr to his profession. His work on gun-shot wounds, which was distributed to every hospital in the army, is in the highest sense worth the reading (1795; in G. Wedekind's "Reports of the French war hospital system" I. p. 294–366, 1797). *Larrey's* principal activity falls within this century.

In *England*, military surgery fared badly. Most of the army surgeons were uneducated quacks, frequently given to drunkenness and practicing their profession in illegitimate ways. When a soldier had served for a little while with a regimental surgeon as an orderly, preparing plasters, then it might happen that he would be appointed assistant, and later successor to the surgeon. Each regiment had a surgeon who was at the same time apothecary, and an assistant; the former received four shillings daily, the latter three shillings, sixpence. Properly, each regiment was to have a hospital, for which the crown provided thirty pounds; yet there was frequently so great need that the sick soldier had to be sheltered in public taverns. There they lay in dirty beds and were badly cared for by their comrades. The hospitals left much to be desired, and were frequently smoky and so narrow that several patients shared one bed. The soldier paid one penny monthly for the purchase of medicines. This money was handled by the surgeon who sought to supplement his own meagre salary out of it, so that in many regiments, the necessary medicines were lacking both in quantity and quality. This lack of money had the direful consequence, that in the middle of the century the surgeons in the field amputated without scruple, because they received £5 for every amputation. Only a few of them possessed good instruments. Sections were seldom made, as anatomic knowledge was too scant and the people had a prejudice against that operation. The station of the regimental surgeon, in accordance with his culture, was contemptible. He was subordinate to the ensign and quartermaster, and had to take much abuse and indignity from the officers when the latter thought that a soldier had remained too long on the sick list. There prevailed also, in the country, the improper custom of allowing the regimental surgeon to fill an officer's place, so that, for instance, he would be sent as a captain with his company upon orders. In the regular troops the surgeon could be sentenced to prison like a common soldier by the youngest officer, and could be subjected to corporal punishment for an offense against the officer.

A few words as to this. Although the discipline in the English army was very mild in comparison to that of other nations, for the Prussian soldier was punished severely if the wind blew the hat from his head, yet the *whip* was much in use. The regimental surgeon was present at the execution of a sentence, and could order a cessation if life was endangered. The flogging was usually about the neck and shoulders; deserters were sentenced to three hundred, sometimes to a thousand stripes, which were given at different times. When the soldier had received a few hundred he was taken into the hospital, and when his wounds were healed he was flogged again. The executioners drew the arms of the delinquent above his head, fastened his wrists to a wooden spike, suspended him in the air and then laid the stripes about his thighs. In the meantime the surgeon saw that the lashes of the whips were sufficiently flexible, for they were very much more painful when they became bloody through long use, and they instructed the executioners to strike chiefly upon the shoulders and not on the neck and ribs. To increase the punishment, they used whips on which the blood was drying. In a few regiments running the gauntlet was in use. The men were placed in two rows and with rods struck at the delinquent who, naked, had to run between them (Hamilton, "Duties of a Regimental Surgeon," 1789). In Austria, under Joseph II., the soldiers were beaten upon the thighs with rods, instead of upon the back as formerly; they also condemned a man to run the gauntlet through three hundred men ten times or more, back and forth; this sometimes resulted in inflammation of the lungs. The Prussian soldier of the Seven Years' War was beaten upon the back with a rod or sword, sometimes contracting "a lung disease in consequence of the considerable concussion."

Among English military surgeons, *John Hunter* stood at the head. His short treatise on gunshot wounds was epoch-making, because it for the first time treated the art of healing, etc., on a physiologic basis. He discussed principally the general surgical questions, and entered less into the different gunshot injuries. He also wrote on the diseases of the troops in Jamaica. In addition to Hunter, *Jackson* of Dublin alone deserves mention; he collected in the American war some good notes on gunshot wounds. On the other hand, there were several illustrious physicians in the English army: Pringle, Don. Monro and Brocklesby. Although the military activity of the English nation could not be compared to that of France and Germany, and the organization of their military medical system was far behind that of France, yet we owe to England a few of the most important innovations, which only came to be fully appreciated a hundred years later. *Pringle first taught the value of fresh air and ventilation in hospitals, Brocklesby first introduced barracks, and Earl Stair made the first specific agreement with the enemy for the protection of the wounded.*

J. Pringle, court physician and physician general of the English army, wrote "Observations on the Diseases of the Army" (1752), a book which has no equal in European literature; he includes in it his researches into the nature of putrefactions and ventilation, and rich experiences in hospital fever. He valued *fresh air* as the chief essential to the cure of diseases, for nothing is more injurious, nothing involves greater danger than infected sick rooms, but this is not believed to its fullest extent. Neither diet nor medicine is of any use, so long as the air is impure and foul. This comes about through stagnant water, heaps of refuse and moldering straw, and through the overcrowding of the hospitals. Such is the case in full, ill-kept barracks and on ships where the people have too little room and are kept on board too long. In order to avoid the diseases arising from such conditions, Pringle recommended that the army change its camp oftener, and in camping in swampy regions to overflow the fields entirely with water. Upon the outbreak of dysentery they should move the camp. In the vaults of the closets, which should be very deep, a thick layer of earth should be thrown every day, and any one should be fined who made use of any other place than the closets. During the progress of a contagious disease, too many patients should not be sent to the hospital, lest the contagion should spread there; the lighter cases of dysentery should be kept in the camp and the others, as far as possible, remain in the regimental hospital. Without this *dispersion of patients* the main hospital would become too greatly overcrowded. The best hospitals were the most airy and roomy houses, barns, stables, granaries and churches. Since fresh air and not warmth was necessary, a large barn should be preferred to a little warm farmhouse. Besides this, Pringle recommended that the regimental hospitals be scattered through several villages, instead of crowded together in one, wherein the maintenance and attendance on the patients were more difficult. He desired that the regiments take their sick with them, so far as the transport wagons could comfortably accommodate them and the diseases would permit it. We have described, in chapter IV, his suggestions for the continual renewal *of fresh air in the hospitals by means of ventilation.*

Don. Monro and *Richard Brocklesby* served under Pringle. They both took part in the Seven Years' War and wrote on hospital fever and field diseases of the English army. Brocklesby has the great honor of having first introduced *barracks*. With the utmost earnestness he recommended these buildings, thrown together out of planks, provided with openings for the admission of light and strewn with straw, for hospitals, on account of the free passage of air. To prevent contagion he had the straw and sand on the floor changed frequently, and in these light board houses he saw many more patients recover than in the low rooms.

October, 1758.—"There was a great crowd of sick brought to the Isle of Wight, and all the little out-buildings, granaries and miserable huts which could be procured for money or for the love of God, were insufficient to accommodate all the sick. In this necessity some of the gentlemen of the hospital advised that a few huts be built in the woods for that purpose, that the floors be covered with planks and the roof with new straw, which would keep out the wind and rain, and that these huts be large enough to accommodate 120 patients or more; the mechanics who undertook the building demanded £40. These huts were actually built, and indeed so badly that they seemed utterly inadequate to their purpose. It was afterward found that the patients who were taken there were obliged to endure extraordinary cold and much dampness, yet the number of deaths was far less than elsewhere, although the patients had the same diseases and were given the same medicines, diet and care. They also recovered more quickly than in the warm, close huts that had been hired about Newport, where they appeared to have usually had better care."

September, 1760.—" . . . I sought back of the camp, in the adjoining field, the spot which was driest and most exposed to the free air, and had the place hollowed out. About the edge of the excavation I had stakes set upright and extending about six feet above the surface of the earth, while between these stakes planks were placed, which I had covered on the weather side with fresh straw; over the planks I had beams laid, which were likewise covered with straw, and in this way I made a hut which was almost large enough for my purpose, where I had sufficient air and where it was warm and dry. It cost 10 guineas to build a roomy and comfortable hut which would hold about forty patients. The straw, which was worth about £5, was upon the order of the general taken from the public stores; in addition the masons of the regiment were ordered to build a fireplace and chimney. . . . But what most deserves attention is, that although many patients were brought to this house who lay sick of the genuine putrid spotted fever, yet only one or at the most two have died of it. I ascribe these fortunate recoveries more to the pure, fresh air which they breathed in this house, than to all the medicines which they were obliged to take every six hours or oftener."

Campaign of 1761.—"As in the Gloucestershire regiment alone nearly a hundred men a day were taken sick, I took occasion to bring to the attention of Colonel Berkeley how easily we could help or overcome this difficulty, if he or the regiment would expend the little money necessary to build such huts, each of which could accommodate some twenty-four or twenty-six men, and should be made by digging five feet below the surface of the earth and covering the planks and beams with a good layer of straw, so that the rain could not get through. As Mr. Berkeley exhibited on every occasion a rare humanity and generosity, I found no difficulty on account of the expense. The carpenters of the regiment were immediately ordered to make the foundation, and he commissioned me to give directions for the building according to my pleasure. In a few hours the solid ground was excavated thirty-one feet in length, eighteen or nineteen feet in width and some five feet in depth. In place of walls, I had the stakes fitted with boards and a roof made above, which was all covered in some way. So I had a roomy, airy, yet sufficiently warm dwelling, into which one could go by means of six steps which I had cut into the earth in order to prevent slipping in wet weather. At one end a fireplace was made of bricks, and out of his boundless humanity the colonel had that part of the ground covered with boards on which the patients could lie very near the fire. In various places in the roof air holes were made, which served for windows and could be opened at pleasure. In a short time three such hospitals were prepared. . . . All the patients received there, with the exception of three at the most, were cured completely, and the number of sick had never been so small as at the end of this campaign."

1762.—"They improved these field hospitals by having a somewhat large, airy porch built at each door, so that the patients who were able to move about somewhat could get fresh air and eat their meals there."

"I am convinced that such huts as I have described above could be built at any time and without difficulty; and since the arrangement of the ordinary hospital can in many respects be so very injurious to the patients, I trust that the measures which I have recommended above will in future receive the approbation and acceptance of those in authority."—("Œconomical and Medic. Observations" from the year 1758-1763, 1764. Trans. by Selle, Berlin. 1772).

He was the first who insisted on placing at the head of a field hospital a physician or a surgeon instead of an officer: "The power of the physician in the hospital should be just as great as that of the commanding officer in the field." (A hundred years were spent in convincing men of the justice of this maxim, for only in the North American war of our own time was the physician the absolute ruler of the hospitals.) The French military hospitals pleased Brocklesby better than the German, in which he especially condemned the crowding together of patients, and the negligence and unskilfulness of the physicians. But far more of the sick and wounded died in the French field hospitals than in the English. Brocklesby indicates the reasons for this in the following words: "As the French surpass all the nations of our time in the knowledge of surgery, so it is well known that they are the most miserable and unskilful physicians in all Europe, especially since their surgeons have sought to impress upon the world that the knowledge of anatomy comprised the highest and most perfect degree of medical science."

The most important step toward the protection of the wounded, which can be regarded as the *precursor of the Geneva Convention*, we also owe to England. The wounded and the sick were for the first time considered, in the year 1689, in a treaty between France and Spain, when each country paid for the care of its wounded in the hospitals of the other, and since that time care has been taken that those from the side of the enemy should have all necessary treatment and nursing. They agreed upon the nature of the attention to be given in the hospitals and each country was to pay for the maintenance of its own soldiers (Gurlt). But it was still customary to transport the patients great distances, by reason of which many of them died. And it was necessary to move the hospitals frequently for the sake of safety, and this also had evil consequences. When, in the year 1743, the English and French were arrayed against each other on German soil, the English Earl Stair, before a battle had taken place, made the proposition to the Duc de Noailles that the hospitals on both sides be declared neutral and be protected by both sides. Noailles agreed to this; it was concluded on June 27, at Dettingen. The soldiers lay upon the damp ground and eight days after the battle about five hundred were taken with the dysentery. The English established a hospital in the village of Fechenheim on the Main, in which, aside from the wounded, about five hundred, mostly dysentery patients, were accommodated. When the Duc de Noailles established his army on the other bank of the Main, opposite this hospital, he notified the English that his soldiers had been expressly ordered not to disturb the hospital in any way. They conducted the whole campaign in this way. Pringle, the physician-general, thus relates it.

Very soon after the battle, on July 18, in Frankfort-on-the-Main, the envoys of the two leaders concluded the actual treaty. The chief provision in this was that the wounded who had fallen into the enemy's hands were to be most carefully treated. Neither physicians, surgeons nor apothecaries were to be held as prisoners of war, but were to be returned as quickly as possible. Each side cared for the wounded and paid the expenses. They could not only receive back the physicians when they desired, but could send them wherever they pleased provided with letters of protection, only they were not allowed to serve again prior to the exchange of prisoners. Sick and wounded were safe in the hospitals and were not considered as prisoners of war. It is seen that these stipulations could scarcely be improved on, although in later wars they were frequently and everywhere violated.

In order to preserve the connection, we will here notice what they *thought in Germany and France of barracks and neutrality agreements.* Colombier considered barns excellent for hospitals, and better than churches, provided sufficient fresh air could be secured. When in the year 1774 a wing of the Hôtel Dieu in Paris burned, Le Roi, a member of the Academy of Sciences, submitted to that body the following proposition: That the number of patients in each hospital should be kept as small as possible, and that in the construction of hospitals special regard should be had for ventilation. As wards abutting directly on each other were unserviceable, he devised a plan by which the wards should stand some distance apart like the tents in the field or the pavilions in the gardens at Marley (standing isolated among the trees). Every ward should be like an island in the open air, so that when the external air was set in motion the air inside the ward would be renewed, without passing through another sick room. There should be several openings in the vaulted roof and also in the floor, communicating by pipes with the outer air, so that a renewal of the air would be constantly taking place; stoves were also to be provided. He anticipated a possible objection to the expense of wards covering so much ground, and asserted that the highest possible cleanliness and the purest air possible should be the only true ornament and glory of a hospital. His propositions were well received but nothing was changed. (Hunczovsky, Med. surg, notes on his travels through England and France, 1783, p. 96.) Bilguer, in Germany, knew the successful experiments which Brocklesby had made with barracks, in the war, and appeared to appreciate their advantages, for he said that they were easily built by the carpenters of the army, they allowed a better supervision of the regimental stewards and avoided the injurious transportation to the hospitals by which so many wounded died. He also shared the view of the English concerning the absolute authority of the physicians and surgeons in the field hospitals. Nothing is said of the fact that Bilguer introduced barracks. The Prussian decree of the year 1787, ordered great sheds to be built for summer use, but the first practical application of barracks in Germany was due, it appears, to Joseph II. In 1789 he had "movable, wooden, adjustable hospitals" built, and found them serviceable. In the War of Liberation several barracks were built. The chief surgeons Görcke and Völtzke, assisted by a very meager force, built three large barracks in the year 1807, when after the battle of Prussian-Eylau, more than eighteen thousand wounded Prussians, Russians and French were crowded together at Königsberg. In the summer of 1813, also, various wooden sheds with 300, 400 and 500 beds were built, and in the autumn were walled up with brick and provided with stoves. Bischoff at that time strenuously opposed the barracks because they were not so healthful and clean as other buildings and were in greater danger of damage by fire.

In regard to the agreement for the protection of the wounded, this idea of Earl Stair, which guaranteed perfect safety to the hospitals, met with perfect approval in Germany during the Seven Years' War. Similar and often literally copied treaties were concluded from that model, between the Austrians and Prussians, in 1757, and between the French and Prussians in 1759; but in practice they were by no means so far advanced. At the end of that war, Baldinger asserted that the misery would be unspeakably diminished if all the princes were in harmony on this one point. Schmucker also expressed the wish that the warring powers would, at the beginning of a war, unite to guarantee safety to the hospitals, so that the latter could be established after the battle in the nearest convenient place. The patients should be allowed to remain here free and until they had completely recovered or, at least until they could be transported without disastrous consequences. Many wounded of both sides would be saved in this way, who under existing conditions perish miserably during the long transportation. It appears to have been an exception in the Seven Years' War, for an Austrian commander to leave a guard and a physician with a wounded Prussian officer when the army advanced. The rule was to take as prisoners the hospital, its physicians and equipment, and to hold them, although the enemy always took the very best care of wounded soldiers, as Theden observed. In France, Colombier contended for neutrality treaties and desired that the generals of both armies should mutually agree never to take the sick as prisoners; and that the defeated army should recover from the victor permission to immediately seek out their wounded upon the battlefield and have them bandaged by their own surgeons. Pourquoi ne pas faire une convention entre les deux armées, qu'on ne prendra jamais les malades, ni les hôpitaux? C'est un acte d'humanité digne de ce siècle. . . On doit respecter l'asyle des blessés et des malades. Il est d'usage qu'on ne les maltraite pas; au contraire les généraux ont une attention singulière à ce qu'ils ne manquent de rien.

When our own time wishes to boast of the humane sentiment of the Geneva Convention it must be remembered that for a hundred years the warring powers, in international agreements have been solicitous of the welfare of the wounded who have fallen into the enemy's hands, and of the protection of hospitals.

With this chapter we close the history of the surgical profession in order to enter more into surgical science. A glance at "German Medicine" may be allowed by way of transition.

(To be continued.)

Senile Heart.—Balfour's rules *(Hospital Times and Medical Gazette)* are in substance as follows: 1. Not less than five hours between meals. 2. No solid food between meals. 3. For all those with weak hearts, the principal meal in the middle of the day and their meals as dry as possible.

SOCIETY PROCEEDINGS.

British Medical Association.

Proceedings of the Section on Medicine at the Sixty-fifth Annual Meeting, held at Montreal, Canada, August 31 to September 4, 1897.

WEDNESDAY, SEPTEMBER 1.

The Section was called to order by STEPHEN MACKENZIE, M.D., who at once delivered his address,

ON THE INFLUENCES THAT HAVE DETERMINED THE PROGRESS OF MEDICINE DURING THE PRECEDING TWO AND A HALF CENTURIES.

It dealt with a history of medicine since the foundation of Canada to the present day, this being suggested by this being the first Meeting held out of Great Britain.

Concerning the improvement in medicine during the past 200 years, the most prominent was the study of anatomy. Physiology is based primarily upon this branch; morbid anatomy too follows it closely. Due prominence was given the microscope in the development of medicine, as one of the connecting links. Due homage was paid the workers in the various branches of medicine for their part in the development of practical medicine, especially Harvey; Laennec, for his development of auscultation in the diseases of the chest; Jenner, Pasteur and Koch and others in carrying out the protective inoculation idea.

Mention was made of the advancement in education, the development of the university idea. The history of modern medicine is largely the history of scientific methods. Great strides have been made in clinical medicine, the greatest being the separation of enteric and typhus fevers; the development of the micro-organism of malaria and the proper classification of the pathologic conditions of the kidney; the opening of the closed book of the nervous system is very prominent. Addison's discoveries of the connection between suprarenal bodies with asthenia, gastric irritation and cutaneous pigmentation; the thyroid gland and its pathologic importance; and the importance of the integrity of the ductless glands of the economy. The development of medical societies and associations is gratifying.

ARTHRITIS DEFORMANS

(rheumatic arthritis), more especially its relation to rheumatism, nervous diseases and tuberculosis, was the subject for discussion.

Dr. JAMES STEWART of Montreal—The remarks were founded on some forty cases under observation in Montreal, viz., twenty males and twenty females. Family history of rheumatism in eight cases; tuberculosis in five cases; history of gonorrhea in the majority of the males, in the females absent in all but one; exposure to cold in five only; worry in four cases; alcoholism in five. In 15 per cent no cause could be ascertained: in 50 per cent. some acute infectious disease was present. Rheumatoid arthritis and nervous diseases; similarity between joint troubles and tabes dorsalis and of rheumatoid arthritis; supposed to be disease of cord; changes in joints; atrophy and sensory disturbances; changes in joints found in tabes, atrophy and hypertrophy, there being little difference between this and syringomyelia, clinically or pathologically, there being polypoid growths and intracellular changes; these intracapsular changes are found early in rheumatoid arthritis; pain is found in the latter, but in the nervous joint troubles not found. Early atrophy of muscles in rheumatoid arthritis probably explained by joint changes, but no loss of sensation is found in this atrophy. The evidence pointing to nervous origin is meager. In the forty reported cases, three cases only had history of tuberculosis. There is an inheritance of arthritic tendency, and history of tuberculosis may lead to rheumatoid arthritis by lowering vitality. History of acute rheumatism often found, viz., four cases of the forty; history of acute attacks, often history of subacute form. In 30 per cent. onset was either like acute or subacute rheumatism. No recognized well-marked dividing line between subacute and chronic rheumatism and rheumatoid arthritis; they are at two ends of scale, the intervening forms it is difficult to classify. It is to be hoped that further bacteriologic examination may develop the infectious nature of rheumatoid arthritis.

Summary.—It is a disease prone to occur in persons of rheumatic tendency. No sharp distinction between various forms of rheumatism; recent investigations point to infectious nature.

Treatment.—Medicinal treatment is unsatisfactory; the most successful is the Scotch douche: dry baths more effectual, sand and superheated dry air; copper cylinders used, the temperature 240 to 300 degrees, inducing perspiration; increased frequency of pulse; twenty cases treated; pain caused in several; gain in weight follows; increase of mobility in many.

Dr. SHINGLETON SMITH of Bristol—The name chosen, rheumatoid arthritis, stamps the whole discussion. The disease is not a rheumatism at all, but an arthritis. One case has developed this idea. A young lady 16 years of age, of good history and family, acute polyarthritis followed in two years by entire and complete crippling. What is gonorrheal rheumatism? A form of blood poisoning, and certainly there must be a source of infection from other parts of the body; we should have some positive evidence of the bacteriologic cause. Some such cause as this, however, will serve better than rheumatism, but until we have this the cause must be held *sub judice.* In the very acute stage during the arthritis, the very active antiseptic treatment may stop it short.

Dr. LINDSAY of Belfast—We all agree that there is a great deal of obscurity hanging over this disease. I have seen no connection between this disease and tuberculosis, but I believe there is a connection between rheumatism in its various phases and this disease. We often see chronic rheumatism slowly develop, in months or years, into rheumatoid arthritis. Cold, exposure, privation are much the same as lead to ordinary rheumatism. Salicylate treatment is ineffectual in rheumatoid arthritis. The tonic line of treatment, cod liver oil and suitable diet, is most often successful.

Prof. ABRAHAM JACOBI of New York—Prof. Stewart did not tell us what arthritis deformans is. What are we to mean by rheumatism? No cases can we conscientiously call rheumatism except the acute articular rheumatism. In rheumatism we have to deal with membranes; in rheumatoid arthritis with the cartilages. This is the real clinical difference.

We have not any coccus localized as a cause, and we should not let this enter into a discussion of this subject.

The only treatment that is of any use is directed toward the nervous system. Arsenic in increasing doses, continued for months and months.

Dr. T. C. WILSON of Philadelphia—I believe that advance of knowledge of disease of joints is hindered by use of the term rheumatism. Rheumatism should be perhaps limited and called rheumatic fever. Senile mono-articular arthritis is really a form of rheumatoid arthritis and not chronic articular rheumatism. Arthritis deformans perhaps can be applied to a wide group of cases. Rheumatoid arthritis of rapidly developing kind resembles clinically the ordinary type of rheumatic fever, but convalescence is not progressive and a series of subacute attacks leaves the joints permanently crippled; all suggest some agency affecting the joints, probably microbic.

Dr. F. C. SHATTUCK of Boston—We know almost absolutely nothing of this disease; we only know it is something like rheumatism. It is one of the opprobria of medicine. As to the presence of micro-organisms in this condition, Dr. Goldthwaite of Boston has been unable to confirm findings of an English observer, who reports findings of micro-organism in arthritic inflammatory fluid. In all cases coming under observation I have tried to discover some concealed source of suppuration, but this connection was traced only in one case.

Dr. MOOREHOUSE of London, Ont.—I have seen quite a number of cases, both multiple and single joints. The latter chiefly of the hip-joint. Two cases, same family: One, boy eight years old, had "ordinary" rheumatism, leaving him with valvular lesion, followed by general arthritis deformans, and he lived to be 22 years of age, and died probably of asthenia; general and complete muscular wasting.

There is a distinct relation between rheumatism and the subject under discussion. The wasting seen to such an extreme extent I believe due to lack of exercise and malnutrition due to the disease.

Dr. J. E. GRAHAM of Toronto—We must have distinct ideas of the pathologic condition, but we clinically have trouble in making diagnosis. There is much advantage from administration of arsenic, more than from any other drug.

Dr. T. D. GRIFFITHS of Swansea—We should try and find out if it is a disease *per se*, or a symptom. Look on it as a symptom of disordered economy, a development of various conditions as the result of various causes: Shock to nervous system, cold, bad nutrition, etc. It is not like gout and smallpox, due to specific causes. The treatment is general, tonic, arsenic, cod liver oil, good diet and fresh air. Find out in the early stage whether it is gout, rheumatism or arthritis deformans; a very difficult thing oftentimes.

Dr. V. P. GIBNEY of New York City, said in his remarks on treatment: Since last fall I have used superheated dry air, a modification of Montreal apparatus, and in general way am satisfied with the results. Function was improved and painful exacerbations removed. I believe that a great deal can be accomplished if hot air can be preceded by surgical procedures, breaking up deformities and at once putting in hot air. Protect these joint in exacerbations; do not use passive motion. Give absolute rest. After exacerbation has passed and you feel cartilaginous and bony deposits beginning resolution, partial motion can be produced by application of special still apparatus. If range of motion 10 or 15 degrees the apparatus should be used to limit motion to this, as exacerbations are often produced by trauma beyond this degree.

Dr. Tyson of Philadelphia—I adhere to views which allow certain relation between the rheumatisms. Treatment has been unsatisfactory. I have never seen even a suggestion of cure. Results are purely palliative. General tonic treatment: Cod liver oil, arsenic and other rational measures.

The Chairman stated that the disease presents so many varied aspects that it is difficult to present any one. The essayist's work is the result of personal work. It is doubtful if anyone will leave with a different opinion from what he had when he entered, because of the lack of the unanimity of opinion; still the discussion is of great practical value. He holds to the view that while arthritis deformans has relations remote to rheumatisms it is a more or less distinct entity. If a person once begins on track of arthritis deformans, its ultimate results will be the same. Clinically, if the disease gets perfectly well without any change in conformation disease, it is not arthritis deformans and no matter what initial clinical symptoms and you have deformity they are cases of arthritis deformans. If you see former cases in a number of years, again with deformity, we are at sea as to whether the primary disease was an acute rheumatism as we first thought.

Dr. Sutton thought the disease was essentially a disease of debility and occurred in families.

Dr. Stewart, in closing the discussion, said that clinically there is often great difficulty in diagnosing cases. There is no clinical or pathologic distinction and many diseases are grouped under this head.

Dr. James Tyson read a paper entitled

THE PROPER USE OF TERMS TO DENOTE MYOCARDIAL CHANGES.

Credit was given Professor Adami of Montreal for his observations on the associated dilatation and hypertrophy of the heart in various pathologic conditions of the heart. The term dilatation should be reserved for enlargement of cavity of heart with associated degeneration of heart walls. In hypertrophous dilatation the walls are not degenerated.

Discussion was participated in by Dr. Whittaker of Cincinnati and Dr. N. S. Davis of Chicago, who said that cardiac fatigue and exhaustion should be used more frequently. Cardiac weakness is often found with beginning pathologic changes which leads to cardiac exhaustion with congestions.

Dr M. H. Fussell of Philadelphia reported

TWO CASES OF HEMOPHILIA.

Case 1.—The grandparents were healthy, but one died of phthisis. Father had had epistaxis in infancy; no tendency to bleeding in the family. When a baby he was cut with a bottle and bleeding followed for some time; at 3 years old had severe epistaxis; at 5 years cut finger bled for a week; soon after he cut scalp and the stitches cut through and still bled for several days until stopped by hair lip pins; tooth pulled, bled since last May. Weighs fifty-six pounds; pale, pigeon-breasted, systolic second sound murmur; venous hum in neck; spleen can be felt; left ankle joint larger than right; numerous subcutaneous hemorrhages of shin. Treated with calcium chlorid. In July had bleeding from nose following a blow.

Case 2.—Male, when eleven months old fell from bed and struck head; bleeding from pulling teeth and cuts on head; again from nose and cut on forehead; at present his nose is bleeding. Subcutaneous hemorrhages on left arm, large and hard. Glandular enlargement; blood contains 40 per cent. hemoglobin. On July 29 he fell on right side from bicycle; has had large subcutaneous hemorrhages on right side, which disappeared in about one month.

Both children given calcium chlorid, mother believes without improvement.

Dr. Allen A. Jones—It is not often that a leucocytosis is found without some inflammatory action somewhere.

A paper by Dr. J. B. McConnell of Montreal entitled "Pyopericardium following Pleuro-pneumonia; Pericardiotomy; Recovery, with Case," was read by title.

Thursday Morning, September 2.

Dr. Robert Saundby of Birmingham, read a paper on

TREATMENT OF DIABETES.

He said that a stereotyped diet should not be prescribed; clinical experience should be the criterion for treatment. Orthodox diet is a pretense. Potatoes are forbidden, while fancy articles containing much carbohydrates are allowed. Carry on weekly weighing, with measuring twenty-four hour urine; if weight is stationary or increasing patient is doing well; even the sugar is increased. Proceed experimentally, allowing more or less starchy foods as indicated.

Polyuria and extreme thirst is best met by diet and opium at night. In strict diet the sugar and starch are entirely excluded. Cakes made of gluten flour previously fermented may be allowed. Breakfast: fat bacon, tea or coffee, and mineral water. If sugar disappears can give experimentally a potato and milk. Light wine may be used cautiously.

From 10,000 grains before treatment, the sugar generally falls to 2,500 to 3,000 grains under treatment. The starch of cereals is more productive of glycosuria then that of potatoes.

Strict diet to begin with, adding carbohydrates as experimental observation will warrant, is the treatment advocated by all foreign observers and has many supporters, though they may be silent in America.

Dr. Sidney Coupland—A strict diet in which all carbohydrates are excluded is impossible. Every case of diabetes is an individual one and in some marked effect is produced by a trivial change in diet. We cannot expect permanent and marked effect from change in diet alone, for we must know more of pathology before any rational treatment can be advocated.

Dr. Shingleton Smith of Bristol—In the diabetes of young people we must go very carefully, but in that of older people we can have much more latitude in the diet. A certain amount of indulgence in carbohydrate craving must be allowed in some cases.

Dr. Ebenezer Duncan of Glasgow—The amount of sugar in the urine in some cases is not a guide as to progress of case. If diabetes is due to marked disease of pancreas no diet will do good. How far we can allow carbohydrates is a matter of experiment, guided by no increase in weakness or loss of muscular power. We must never give way to cravings of the patient for they invariably get rapidly worse.

Dr. Tyson of Philadelphia—Dr. Saundby's treatment is practically that of the speaker. It is often easy to find cases drop into one of two categories, mild and severe. In those from whose urine it is easy to eliminate sugar by diet, they are relieved with varying facility and ease. The cases of glycosuria will run over to diabetes if let alone. Cases containing under 2 per cent. of sugar in urine have been cured. Keep under observation, pure proteid diet being best, at least use it once a month for two days, and sugar will be found to disappear entirely. Cases of the second class are those in which pure meat diet will not entirely eliminate sugar; how far shall we limit the diet? A certain proportion of sugar is of itself harmful in the urine, and the diet should be restricted.

A pure proteid diet has been stated, by Dr. Munson, to be harmful, increasing the diacetic acid in the urine, this being responsible oftentimes for the coma. These foreign substances are due to the breaking up of the body albumin, but the speaker's views do not entirely coincide with those of Dr. Munson. It is practically impossible to keep one on a purely proteid diet, and the latitude which we are forced to permit will prevent the formation of these substances.

Prof. Abraham Jacobi of New York City—A good deal of what we know and do in the way of dietetic treatment is not the result of experimententation as much as of experience. Diet must be changed according to age. The very young will not stand strict carbohydrates; the very old much better. Many do not thrive on any diet. If they emaciate, the carbohydrates must be increased. The younger the child, the quicker they die, but they last longer by entirely restricting the carbohydrates. The question of milk: A diabetic never gets worse with milk, the speaker gives milk in every case and they are better for it. Duncan's recommendation is not best. Give milk in any form it can be taken. *Old persons do less well on strict diet than on* mixed diet.

Dr. Lindsay of Belfast—We must pick our cases. A good deal of liberty in diet is safe in older people, but experience has been uniformly unfavorable in the very young. The clinical course is best to be watched rather than the urine.

Dr. Tyson, speaking again, said that in the mild cases spoken of, the milk diet can be given, but without any special benefit or harm: safe with other diet. Not so though in the severe form. The urine as a rule is the best guide as to the condition of patient.

Dr. Wright of Ottawa—From experience I believe there is a distinction between glycosuria and diabetes, the former occurring chiefly in elderly people and in them there is no pathologic condition. Cases of healthy young men, under 25 years of age, sometimes show sugar in the urine without polyuria or other symptoms. These are found only when they present themselves for life insurance examination. In cas-man, unusually well developed, never ill, there is a glycosuria, absolutely without symptoms.

The speaker wished to know of any treatment, dietetic or otherwise, indicated.

The CHAIRMAN said that we are very prone to be routinist and the essay was of great importance in showing how much more beneficial it is to find out how much of carbohydrates a patient can stand and desires, and that the weight and clinical condition of the patient should be the index as to his condition, and not the urine and its sugar.

Dr. SAUNDBY, in closing the discussion, said that he did not advocate *latitude*, but the reverse, giving a diet which was tolerable to them, even in children. A little carbohydrate can be given, especially potato, for it agrees when no other form of carbohydrate can be tolerated. Four to six ounces can be given and well tolerated. All diabetic children die and we should try to make their lives as tolerable as may be. In each case it is an experiment. The doctor should only be required to analyze the urine. He has always used a milk diet, with others, for years, giving some daily with advantage. If during the first week we decide to watch the sugar, do not give it. The percentage of sugar is misleading; rather get the total amount in grains or grams. Polyuria, thirst and increase of sugar are guides. Loss of weight permits a certain increase of sugar, even if sugar in urine increases.

Dr. EBENEZER DUNCAN of Glasgow read a paper entitled

TREATMENT OF DIABETES BY URANIUM NITRATE.

Dr. West's paper first attracted the writer's attention to this remedy. Increase in weight and decreased thirst being the first result noticed. The late reports from various sources have not been so favorable. Experimental researches show that the remedy produces a nephritis. The author's observation shows it to be a safe remedy in 15 or 20 grain doses daily. Several cases of typical diabetes were reported, in which the nitrate of uranium was used after a trial of diabetic treatment, the result being in one case the urine reduced from 9 to 3 pints, the sugar from 40 grains to 10 grains, and proportionate increase in weight. The diminution in sugar and urine and increase in weight is due, the author believes, to the sugar consuming cells being strangulated by the uranium nitrate. He believes the remedy is of most use in neurogenous form of diabetes and practically none in the pancreatic form.

Dr. TYSON of Philadelphia used uranium twenty years ago and felt that it was of no use, but then used it in 2 grain doses t. i. d. Lately he has again been using it, but had to cease on account of producing diarrhea (in 5 grain doses). He had been afraid of such large doses but will try it again.

Dr. SAUNDBY of Birmingham had used the remedy in small doses and abandoned it. Since West's paper he had seen some [illegible]d in larger doses, but does not consider at all that it is a pecific.

Dr. DUNCAN, in reply, said he had not asserted it was a specific remedy, but he did say that improvement followed in every case. The diarrhea he believed was due to over-feeding, as undigested food was passed.

Dr. J. E. GRAHAM of Toronto read a paper entitled

CROSSED HEMIPLEGIA DUE TO INJURY TO THE PONS VAROLII

and exhibited the patient.

Accident occurred when the boy was eighteen months old. Nothing is known of family history. A stick entered the mouth and passed through the junction of the hard and soft palate. Considerable force was used to remove it. He cried from 5 to 11 P.M., then vomited blood, and convulsions occurred at intervals for three days; on the third night paralysis of right leg and arm, and face on opposite side. Swallowed with difficulty. In bed seven months. Convulsions nearly every day, and for five years they have occurred at night. Tonic is followed by general epileptiform convulsions; more frequent when constipated. Mind clear, but not as bright as others. Right side colder than other (these notes made five years ago). Scar half inch long on left side of palate at present.

Considerable atrophy of right side. Face drawn to left side; perhaps paralysis; wrist moved with difficulty; elbow well; foot half amount of flexion; awkward limp; patellar reflex exaggerated on right side; ankle clonus present.

Note made today: Face flushed; extremities cold; pupils equal; no paresis or nystagmus; contractures of elbow, wrist and fingers of right side; atrophy of right lower extremity; complete flexure of ankle impossible: intelligence below average; sensation normal, save right upper extremity, slower than other side; ankle clonus on right side; No athetoid movements. The paralyzed arm reacts to electricity more readily than left arm. Case of hemiplegia showing hemiplegia of whole right side and on left side of face also.

The splinter passed through into the inside of skull, and inflammatory lesion extended involving sensory sense as well as motor.

Dr. E. B. ANGELL had under observation a case in which there was a tumor of the pons in which there was an absence of reaction of degeneration. In the contraction of the leg, free incision of the tendons certainly gives increased function.

Dr. HENRY KOPLIK of New York read a paper entitled

BACTERIOLOGY OF PERTUSSIS.

Interesting cultures were exhibited in the department of bacteriology. Kohn and Neuman have made original investigations, but the whole matter was left somewhat chaotic. They were unable to say whether the diplococcus isolated was specific.

The author used serum from human blood, using hydrocele fluid. This will not prove favorable to other micrococci, streptococci not growing on this medium. In pertussis we have small white pellets which observers say contain bacillus; composed of epithelioid cells and mucus and contains small bacillus. If complicated by pneumonia, pellets not found, and it is difficult to isolate bacillus; uncomplicated cases can isolate it easily. In sixteen cases he has found it grown on hydrocele fluid in thirteen. Delicate, punctate coating, and grows from this on agar and gelatin; not on potato; in air; stains with methyl blue. It is motile, thinner than diphtheria bacillus, .8 micro-millimeters long. Only .3 in breadth, an exceedingly delicate micro-organism.

Impossible to produce symptoms of pertussis in lower animals and only on human subjects can it be produced.

Dr. JAMES GRANT—In the treatment of children with pertussis, vaccination frequently influenced the disease, modifying it greatly. I ask the author why this is so? What is the action of the vaccination on the bacteriologic forms?

Dr. KOPLIK, in reply, said he could not explain the phenomenon unless by referring to the action of erysipelas on malignant growths being similar.

A paper was read by Dr. JOHN H. MUSSER of Philadelphia entitled

THE DISAPPEARANCE OF ENDOCARDIAL MURMURS, PRESUMABLY ORGANIC.

Permanency of murmurs serve to aid diagnosis between anemic murmurs. Murmurs disappear and reappear when result of valvulitis, as mitral stenosis and aortic regurgitation. No report has been made of disappearance of aortic stenosis or of tricuspid murmurs. Peculiar accentuation of second sound is an important associated sign of mitral stenosis. Mitral obstruction murmurs are variable. It may disappear temporarily or permanently in the course of the disease or afterward. Nearly all authors confirm this as quoted by the author: Tyson, Walsh, Strümpell, Loomis, Hayden, Bramwell, Grieves, Williams, Boyd, Saunders and others, various causes being assigned. Presystolic murmur may be mistaken for this. Aortic regurgitation is the most persistent of all organic murmurs; some of the above authors stating it is rarely that it disappears. He reported a case of vanishing aortic regurgitation after being present one year. Patient died of pulmonary edema and autopsy showed a large calcareous spot on each leaflet; pressing these deposits down rendered the valve competent. We have pseudo-insufficiency which must be excluded in making diagnosis, also dilatation of ascending aorta and yielding of sinuses of Valsalva. In mitral regurgitation murmur which disappears, it is difficult to tell whether it was organic or inorganic. Other organic conditions causing regurgitation may be mentioned; a rupture of tendon of leaflet which sometimes floated in the cavity, sometimes between leaflets.

The following papers were read by title: "A Contribution to the Subject of Brain Tumors and Their Surgical Treatment," by Dr. M. Allen Starr of New York city; "The Enteric Fever of Armies, Contrasting the Disease in Tropical, Subtropical and Temperate Climates," by Surgeon-Major Hamilton of Plymouth; "Reynaud's Disease, Following Protracted General Erythema," by Dr. A. McPhedran of Toronto; "A Few Observations on Bermuda," by Surgeon-Captain Cummins of Bermuda; "Notes on Bermuda as a Winter Resort," by Dr. Eldor Harvey of Bermuda.

American Pharmaceutical Association.

IMPORTANT ACTION OF THE AMERICAN PHARMACEUTICAL ASSOCIATION.

The following Preamble and Resolutions was presented to the AMERICAN MEDICAL ASSOCIATION by the delegation from the American Pharmaceutical Association at the last annual meeting of the former ASSOCIATION held in Philadelphia in June.

The document was referred back to the Pharmaceutical Association for ratification, and passed unanimously by that body in general session at its recent annual meeting held at Lake Minnetonka, Minn. It was then referred to the American Medical Association for final action at the next annual meeting in 1898, at Denver:

PREAMBLE AND RESOLUTIONS.

"To the American Medical Association:

"We, a delegation of pharmacists, representing every section of the United States, being appointed by the American Pharmaceutical Association to attend the meeting of the American Medical Association, in Philadelphia, the first Tuesday in June, 1897, do herewith present to your honorable body the following preamble and resolutions, hoping that your honorable body will endorse the same that it may express the sense of the National Medical and Pharmaceutical societies in relation to matters of mutual interest to the professions of medicine and pharmacy.

1. Whereas, Secrecy in regard to the origin, nature, composition, and methods of preparing medicine is a hindrance to science in that it conceals knowledge and presents an open door to fraud, and

2. Whereas, Monopolies in medical products enable medical monopolists to create a fictitious demand for the same by advertising the favorable side only, and suppressing anything that might injure sales, and

3. Whereas, Such a method of advertising gives undue importance to medical novelties, and

4. Whereas, Secrecy and monopoly and misleading methods of advertising are contrary to beneficence and professional liberality, and

5. Whereas, Pharmacy, or the science and art of preparing medicine is part of medical science and practice, and physicians are dependent upon pharmacists for the selection, preparation and standardization of medicine; for the publication of the knowledge of drugs and the methods of preparing them for therapeutic use; for the establishment of medicinal preparations in scientific forms that the knowledge thereof may be intelligible to future generations, and form part of medical literature, and take its place in text books for the instruction of students about to enter the professions of medicine and pharmacy and thus form part of what is known as the science of medicine, and

6. Whereas, The "United States Pharmacopeia," being devoted to the drugs and preparations used by physicians in treating the sick with directions for preparing the same, should contain a list of the newer drugs and preparations introduced to the materia medica, with processes for preparing them, and standards for their excellence and purity, and

7. Whereas, Many of the articles advertised in the medical and pharmaceutic journals claiming to be true pharmaceutic preparations are not admitted into the United States Pharmacopeia, though some of them are of sufficient value to be made official, for the reason that their only names are claimed as private property, and their constituents are not divulged, and

8. Whereas, The composition or origin of many of these articles are trade secrets, a danger threatens medical literature, for without a knowledge of their drug composition, pharmacopeial references to them as remedies for the treatment of disease is meaningless from a scientific standpoint, therefore, be it

1. *Resolved*, That we, as representing the profession of pharmacy, do hereby express our condemnation of secrecy and monopoly in medical products, and at the same time express our desire that the medical profession shall unite with the profession of pharmacy in raising the standard of professional and scientific requirements so that the practice of pharmacy shall be maintained at its true position as a part of medical science and practice, hoping that by so doing the time may soon come when physicians and pharmacists may work together in harmony in promoting progress in the knowledge of medicine, and in the application of medical agents to the relief of human suffering. We do hereby accept the definition of a secret remedy given by the official Medical Board of Saxony: "Secret remedies are all those agents sold for the prevention and cure of disease of man and animals, of which the ingredients, percentage composition and method of preparation are not made public when first announced for sale. Such information must be complete and exact in readily comprehensible language and made known to all desirous of such information." And be it

2. *Resolved*, That we request that all manufacturers of pharmaceutic preparations shall comply with scientific and professional requirements; shall throw open every medical product to legitimate competition; shall publish the working formulæ for all medicinal preparations or compounds; shall give to each preparation on the market, when first introduced, a name under which all may manufacture and deal in it, such name to be appropriate and descriptive of the article to which it is applied, and compatible with scientific nomenclature; and shall furnish the Committee of Revision of the "United States Pharmacopeia," if requested, with the composition of each secret or semisecret combination, so that the article described, if found worthy, may be made official in the "Pharmacopeia," and be it

3. *Resolved*, That we recognize the commercial element in pharmacy which requires that capital invested in the manufacture of medicine should receive legitimate protection, provided it is employed in accordance with beneficence and not used for the purpose of misleading the public by lying advertisements and injuring the public health; therefore, while not sanctioning the patenting of medicinal products themselves, we do sanction the patenting of machinery and processes for manufacturing medicines, provided that they are really new and useful inventions, and providing the applications for patents are not drawn up in such a manner as to create monopolies in the products themselves so that others can not manufacture them by other machinery and by the use of other processes. By this, we mean to say that all medical products should be open to free competition, and as the supreme court would not sustain the patent of Professor Morse because the application was so drawn up as not only to protect him in the use of his machinery and apparatus, but to give him a monopoly in the transmission of messages by electricity, and thus to hinder progress in the development of a most valuable discovery, so the courts should not sustain any patent which will create a monopoly in the manufacture and sale of a medicinal agent or composition of matter used in the relief of human suffering, and be it

4. *Resolved*, That it is our purpose to do away with the use of fanciful words employed as titles for medicinal preparations to the confusion of medical nomenclature, and replace the same by legitimate trade marks, or marks of trade used as commercial signatures to distinguish between two or more brands of the same article as manufactured by various firms, and be it

5. *Resolved*, That sufficient pharmacy should be taught in our medical colleges to enable students entering the practice of medicine to discriminate between persons engaged in the legitimate practice of that art, and those pretenders practicing pharmacal quackery; and that sufficient knowledge of physiology and therapy should be taught in pharmaceutic colleges to enlarge the scope of knowledge of pharmaceutic students so that they may afterward realize the responsibility of their own vocation, limit their practice to its proper sphere, and not trench on the prerogatives of physicians, that the medical and pharmaceutic professions may hereafter work in harmony for the purpose of promoting knowledge in medical science in all its departments, raising the standard of education in both professions, and furnishing the public with a higher class of medical and pharmacal service, and be it

6. *Resolved*, That the United States Pharmacopeia should be made a text-book in both medical as well as pharmaceutic colleges, that physicians and pharmacists should be urged to provide themselves with copies of that work, that both professions should be urged to take more interest in its decennial revision, sending accredited delegates from medical and pharmaceutic societies thoroughly instructed as representatives to the convention for revising the "Pharmacopeia," and that the increased revenue derived by the Committee on Revision from the larger demand for the "Pharmacopeia" thus engendered be devoted to improving that work by means of original investigation and other methods that may be suggested.

PRACTICAL NOTES.

Turpentine in Mumps.—A note from the *Massachusetts Medical Journal* states that in usual doses, according to patient's age, turpentine is a specific against mumps. Recoveries are quick and without metastasis.

Leeches for Influenza.—Great relief has been obtained in severe coryza by applying a couple of leeches to the nasal septum, after disinfection, protecting the nose with a cotton tampon inserted on each side. The wound made by the leeches is painted with collodion. D'Aiuto, who suggests the treatment, adds that it should be restricted to elderly people and extreme cases.—*Therap. Woch.*, August 1.

Dosage of Colchicum in Gout.—Professor Schultz announces that the failures in colchicum in gout are due to errors in the dosage, and he announces as the result of considerable research that the best formula is the tincture of colchicum seeds diluted with alcohol 1-10, of which 20 to 40 drops are taken during the day.—*Semaine Méd.*, August 18.

The Menthol Pencil for Insect Bites.—Immediate relief is experienced from the bite of an insect, mosquito, etc., if the spot is rubbed with an ordinary menthol pencil or, better still, painted with a solution of menthol in sulph. ether, 1 to 10 or 1 to 5.—From *Corr. Bl. f. Schw. Aerzte* No. 14, in *Therap. Woch.*, August 1.

How to Prevent Intolerance of Martial Medication.—Iron is well tolerated by the stomach when the secretion of hydrochloric acid is normal or below normal. The intolerance only occurs when there is excessive secretion. This can be remedied by appropriate alimentation or alkalines, and then the iron can be administered to advantage.— N. Buzdygan, *Semaine Méd.*, August 18.

The Success of Salol in Generalized Scleroderma is announced by A. Philippson in the *Deutsche Med. Woch.* of August 12, although he has only two cases to report. But the improvement in both was marked and permanent from the start. The puritis ceased at once and the skin regained its suppleness and the members their flexibility in eighteen months in the first, a very severe case, and a little later in the other, a woman of 69. The dose in the first case (a young man) was 3 to 4 grams a day, in the other 1.5 to 2 grams. No inconveniences were observed from its prolonged use. Massage and gymnastics were ordered as indicated.

Differentiation of Epithelioma and Syphilitic Chancre of the Lip.—Chancres of the lower lip and chin sometimes acquire such dimensions that they are mistaken for epithelioma, but the surface is more regular; the edges do not project and turn over; the blood exudes through numbers of infinitesimal openings without the free hemorrhage of an epithelioma; the progress of the lesion is much more rapid and the satellite adenopathy appears by the close of the first week, and the secondary eruptions toward the end of the first month.—*Gaz. M. de Liège* from *Jour. de M. et de C. Prov.*, June 10.

Whooping Cough Treated with Sulphate of Quinin, Resorcin and .—Dr. Leuriaux of Brussels recently communicated to the [illegible] Acad. de Méd., his success with insufflation of a powder composed of these substances which he considers an absolute specific. He reported twenty-six observations in detail, and stated that he had been observing its action in more than 200 cases. He ascribes the disease to an infective nasopharyngeal catarrh, which can be checked by the insufflations, while the tracheobronchic troubles are merely ulterior complications—*Bulletin*, August 3.

Dyspeptic Albuminuria.—Robin ascribes this trouble to the passage of undigested albumin into the urine, where it acts as a foreign substance. It is readily curable at first, when it is only intermittent, but after the chronic stage has arrived the proportion of cures is only 30 to 35 per cent. The treatment consists in merely regulating the diet, adapting it to each case as the albumin is found to increase or decrease with a vegetable, animal or mixed diet. A strictly milk diet is indicated for many patients, suspended if they begin to lose in weight.—*Bulletin de l'Acad. de Méd.*, August 17.

Success of Argonin in Gonorrhea.—Basing his assertions on the effects obtained in thirty-three cases of more or less chronic gonorrhea, none recent, Zydlovitsch recommends argonin as superior to all other medication for this purpose. It causes the rapid disappearance of the gonococci; does not aggravate the pathologic process, but attenuates it. It should be continued until no gonococci are discovered in the course of three to five examinations at three day intervals. The argonin is injected into the anterior portion of the urethra in a 3 to 200 solution five times a day, and retained five minutes. The posterior portion is treated with a 2.5 to 100 solution instilled. The consecutive catarrh with astringents.—*Gaz. Méd. de Liège*, August 5.

Jonnesco's Method of Nephropexy is described and illustrated in his new journal, the *Revista de Chirurgie*, published at Bucharest (No. 4). After an incision parallel to the twelfth rib or if too short the eleventh, the kidney is brought up to the wound. The adipose capsule is detached and turned back from the entire outer side of the kidney, which is then fastened to the rib by three double silk threads, or better still by two U-shaped pieces of silver wire, each end inserted separately with an Emmett needle passing through the skin, through the M. sacrolumbaris, the lower aponeurosis, and through the fibrous capsule on the rear side of the kidney, through the renal parenchyma 1.5 c.m. from the outer side of the organ, then through the fibrous capsule on the other surface through the periosteum of the twelfth rib and finally out again through all the layers, 3 cm. beyond the wound. The ends of the threads are tied over a long roll of sterile gauze on each side of the wound, and the organ is thus fastened to the rib at each end and in the middle, with the ureter in its normal position. He has performed this operation ten times on patients and many times experimentally. He is careful to keep his patient in bed twenty days, and removes all the threads or wires the tenth day, thus obviating all the inconveniences of permanent threads. The adhesions between the decorticated parenchymatous surface, the rib and the muscular tissues, form a remarkably firm support, and "all the disadvantages of other methods are absent."

Quinin Treatment of Meniere's Disease.—The sulphate of quinin is the specific for this annoying affection, but the technique of its administration is all important, Gilles de la Tourette states in a six page article on the subject in the *Semaine Méd.*, of August 18. He does not hesitate to send his patient to a sanitarium if he thinks his instructions will not be carried out to the letter at home. After consulting with a specialist, a plug of cerumen may prove the cause of the trouble—and if there is no acute affection of the tympanum, he proscribes all local treatment or intervention, and institutes a preparatory system of alimentation consisting chiefly of milk, for the week previous, after which the milk is dropped, as the sulphate of quinin coagulates it. The dose is important and should be carefully studied, varying from one-half to one gram (usually 0.75 gram) per day, divided into 3 or 4 doses, taken between meals, with a certain amount of water to prevent injury to the stomach. This course should be followed faithfully for fifteen days, warning the patient that his symptoms will grow worse at first, confining him probably to his bed. In some cases one course is sufficient to effect a complete cure, but a second course is required in most cases, and occasionally a third. An interval of two weeks should be allowed between the first and second, and of a month or two between the second and third. Perseverance is the *sin qua non* of success and the cases cured with one course require supervision for a long while afterward, so as to commence the following course promptly when indicated by a recurrence of the troubles. If there is intolerance of the quinin, it can be administered per rectum, 0.30 to 0.40, in an emulsion with the yolk of an egg, night and morning. This method is uncertain; if it fails the only recourse is to salicylate of soda, 2 to 4 grams a day for two weeks as above. The quinin acts upon the hyperexcitability of the labyrinth, which is the source of the trouble, but it has no effect upon sclerosis of the tympanum or anchylosis of the ossicles. Consequently if there is deafness from this cause, this treatment will not cure it. The general belief that quinin will cause deafness he considers, with Charcot, absolutely unfounded, and cites patients who claimed their hearing was improved by the quinin treatment.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 61 Market Street (Occidental Buildings), Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, Venetian Building, Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL *of the Association* will be forwarded regularly.

Gentlemen already members of the Association should send their annual subscription to the Treasurer, or direct to the JOURNAL office.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the *Editor*, and all communications relative to the business of the JOURNAL, proof sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street (Occidental Buildings), Chicago.

Original communications are only received with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, SEPTEMBER 18, 1897.

EVIDENCE WHICH TENDS TO WEAKEN THE VALUE OF WIDAL'S TYPHOID AGGLUTINATION REACTION.

To one who listened to the recent elaborate and very valuable discussion upon sero-diagnosis in typhoid fever at the last meeting of the ASSOCIATION, the testimony upon the value of this test seemed far from convincing. The discussion was carried on by some of the most prominent bacteriologists in America and dwelt in considerable detail upon many features of the WIDAL reaction. Still there was a diversity of opinion upon many essential features, and even after the report of the special committee appointed by the Chairman to harmonize the views expressed, there was still elements of uncertainty about the matter.

A great deal was said about the importance of the technique to be employed in making the WIDAL serum test, and still there was scarcely a single point in the methods in which two observers agreed. Opinion differed as to the source of the serum, whether it should be from blood, from blisters, or whether dried blood should be employed; though the reaction was obtained by serum from any of these sources. The dilution of the serum was another point upon which opinions varied, and this held true for the source, age and virulence of the typhoid culture; for the dilution of the bacterial emulsion, and for the proportion of emulsion and serum. Then came the question of the agglutination reaction. What should be considered a reaction? How far should loss of motility and agglutination proper be given value? What should be considered the time limit of a reaction?

The single point upon which an almost unanimous opinion was obtained was with reference to the clinical value of the WIDAL reaction as a sign of typhoid fever.

The diversity of views expressed by these representative American scientists is only a repetition of the opinions of observers in all parts of the world who have discussed this question, and while these discussions, especially when conducted as systematically as the one at Philadelphia, will soon enable us to decide upon the merits of the case; they all seem to foreshadow a disappointment for those enthusiasts who failed to exercise a due conservatism in forming their judgment upon the value of the WIDAL test. Even from the clinical standpoint there can scarcely be a doubt that the reaction has occasionally failed to appear when the blood of a typhoid fever patient has been used; and, on the other hand, the reaction has occasionally been obtained in a variety of other diseases. How far these results have been due to faulty technique is impossible to say, especially when it is so hard to decide upon what is to be regarded as *the correct technique.*

It is well known among bacteriologists that there is a close biologic relationship between the colon bacillus and the bacillus of typhoid fever; so close indeed is this relationship that many bacteriologists have come to regard the common bacillus of the intestine and the bacillus of typhoid fever as varieties of the same species. This view has been advanced from time to time, and is again strongly suggested in the elaborate studies by ADELAIDE PECKHAM (*The Journal of Experimental Medicine,* Vol. II, No. V, 1897). Among other interesting and valuable studies upon these bacilli, this author has tested a large number of colon and typhoid bacilli from various sources as to their reaction with typhoid blood serum. A considerable number of cultures of what were regarded as typical typhoid bacilli failed to give a characteristic reaction, while at least two out of nineteen typical cultures of B. coli responded perfectly to the serum test. These results are quite in accord with all the other so called specific methods for the differentiation of the typhoid and colon group of bacteria, and they would seem to be a serious blow to the WIDAL tests, for upon the specificity of the reaction hinges much of its value in clinical diagnosis. If the colon bacillus will respond to the agglutination effect of serum from typhoid patients, why will not the typhoid bacillus be agglutinated by the blood serum from colon bacillus infections? We believe this will be found to be the case, and in support of this opinion we have succeeded in obtaining a typical agglutination reaction with typhoid cultures in five out of seven cases of suppurative appendicitis by using the dried blood after the directions of JOHNSTON. In three out of the five positive cases a bacillus corresponding perfectly to the colon type was alone isolated from the pus obtained at operation. The other cases had already been operated upon and no analysis of the pus was made. Such results seem suggestive to say the least, and they should be followed up.

Another curious feature about the agglutination of the typhoid bacillus has just been brought out by the experiments of Malvoz (*Annales de l'Institut Pasteur*, Tome XL, No. 7, 1897), who has succeeded in producing a reaction with typhoid bacilli, similar to that produced by typhoid serum, by various chemic substances. He mentions especially formaldehyde, corrosive sublimate, peroxid of hydrogen, and strong alcohol. Among the anilin colors, crysoidin, vesuvin, and safranin have the property of provoking a perfect agglutination even in very dilute solutions. Malvoz attempts to use this agglutinative action of chemicals for the differentiation of colon and typhoid bacilli, and appears to find a considerable difference in the behavior of these two types. On this point, however, judgment must be cautiously withheld, for in the failure of so many other differential tests it is improbable that this one of agglutination by chemic reagents will prove specific. As to the significance of these experiments in explaining the *modus operandi* of the agglutination reaction no opinion can at present be formed, and this is equally true as regards their bearing upon the clinical side of Widal's test.

OPIUM COMA OR MENINGEAL TUBERCULOSIS.

In a recent article on possible medico-legal relations of miliary tuberculosis, Dr. F. P. Weber of London, England, reports the following case:[1]

A 19 year old man was brought to the hospital under Dr. Weber's charge, suffering from febrile delirium. He could answer no questions and there was no history obtainable. The physical signs were not quite the same over both pulmonary apices, which caused meningeal tuberculosis to be suspected. There was, however, much albuminuria, a condition not usually associated with meningeal tuberculosis and further, neither the results of ophthalmoscopic examination nor special nervous symptoms were available. It was therefore possible that the patient had taken poison acting on the kidneys and nervous system. He died some days later. The postmortem examination cleared up the diagnosis. There were also tubercles in the lungs, and miliary tuberculosis of the mucous membrane of the glottis. The kidney affection present was parenchymatous and probably due to the bacillary toxins which had to be excreted. Dr. Weber remarks that cases of meningeal tuberculosis in adults are probably not rare, in which, if there were absence of past history, temporary suspicion of poison or foul play might be entertained. In the forgoing case the absence of past history and the presence of much albumin in the urine led to doubt in the diagnosis. In such cases the doubtful points are cleared up by postmortem examination.

Some ten years ago, in a paper read before the Chicago Medical Society[2] Dr. W. T. Belfield called attention to the like forensic aspects of meningeal tuberculosis. He pointed out that, given a case of coma preceded by vomiting and headache, occurring in a person of hitherto seemingly perfect health, having a suspicious abdominal enlargement, the possibility of an insidious meningeal tuberculosis should always be considered. In this paper Dr. Belfield pointed out that clinicians had frequently noticed the proteiform symptoms of meningeal tuberculosis. Bristowe, for example, had remarked that: "No disease is more protean in its features and probably none simulates so many other disorders. In some cases, indeed, even when the brain inflammation is uncomplicated, drowsiness and coma are the only symptoms ever recognized. In many cases the early stage of the disease is mistaken for inebriation." S. Wilks had reported several cases in which meningeal tuberculosis in adults had every obscure early symptom and mimicked the symptoms of opium poisoning. S. J. Gee reported several cases in which meningeal tuberculosis mimicked every variety of neurosis from simple hysteria down. Ross calls attention to the obscurity of the early symptoms of meningeal tuberculosis. Huguenin says that "often the differential diagnosis can not be made in the beginning between congestive cerebral hyperemia (essentially the condition produced by opium) and meningeal tuberculosis. If the individual be relatively healthy precedent to the breaking out of the meningitis, a prodomal period is often wanting in carefully observed cases and the disease begins with head symptoms in the midst of apparently good health.

Dr. Belfield's own case was that of a girl about 20 years old who had always had excellent health. Three sisters are still living, and neither they, the parents, nor any of the relatives, so far as known, have ever shown symptoms of tuberculosis. The present generation are examples of perfect health and this girl was in many respects seemingly the healthiest of the lot. Until five days before her death her health was as usual; then one evening she complained of feeling ill, her head ached; she vomited without apparent cause. She lay down, drank a cup of tea, and was all right. The same thing happened the next day and she complained of extreme headache. On the third day, with the exception of severe headache and seemingly causeless vomiting, she remained in her usual health. The evening before her death she was at the theater and came home about eleven o'clock, going to bed with one of her sisters. During the night the sister was several times awakened by the extraordinary breathing of the patient, which was very hard and loud. She shook her and the abnormal breathing ceased. In the morning it was found impossible to awaken her. She was breathing very deeply and slowly and could not be roused. Physicians were summoned, all of whom pronounced it a case of opium poisoning. The symptoms observed were stertorous breathing sometimes as slow as four or five per minute, contracted pupils, a suggestion of strabismus, and a rather warm surface. The pulse was remarkably good (about 80), similar to the pulse of a healthy person; the skin was not moist and clammy. The usual measures for opium poisoning were adopted. Mustard was given at once and as soon as a tube could be procured the stomach was pumped out. Minute doses of atropin were injected hypodermically, the patient receiving about a fortieth of a grain in three injections. The breathing improved very much after these injections, coming up to twelve and fifteen per minute, the pulse also quickened but suddenly the pulse flickered and went out and breathing stopped. On the following day Drs. **Krost** and **Belfield** made a postmortem examination of the head and abdomen. The brain was not hyperemic, there was no venous congestion; the pupils were widely dilated; the membranes of the brain were adherent to the brain substance and on stripping close they were found on close examination to be studded with numerous miliary tubercles. On opening the abdominal cavity the intestines bulged out and their surface was thickly studded with miliary tubercles. There was extreme tuberculosis of the peritoneum. The mesenteric glands were large and cheesy. The right ovary contained a rupture cyst about as large as a fist. That the rupture was antemortem was evident from the fact that the inner surface of the cyst was intensely congested and there was a good deal of coagulated blood in its cavity. Dr. **Belfield** points out that when it is remembered that the pulse was natural, that the surface was not cool and clammy and that their was a tendency to strabismus it becomes evident that death resulted from the tuberculosis, aided perhaps by rupture of the cyst. No opium could be discovered anywhere around. The patient's general disposition and circumstance were such as to forbid the presumption by her friends that she could have taken poison.

---

[1] Lancet, Aug. 7, 1897.

[2] Western Medical Reporter, February, 1887.

The case seems to have been another instance of sudden coma incident to tubercular meningitis. It is of extreme interest as showing how insidious a course miliary tuberculosis of the serous membranes may take. The only abnormal features known to her family was an unusual fulness and hardness of the abdomen developed during the last year of her life. The symptoms hinting at possible tuberculosis were the peculiar breathing (which resembles that described by **Trousseau** as characteristic of tuberculosis), and the strabismus on which **Bristowe** lays stress. At the same time it must be remembered that these symptoms exceptionally complicate opium coma. Meningeal tuberculosis in adults is generally secondary to abdominal tuberculosis and of this there is decided evidence in the peculiar abdominal enlargement observed by the friends long precedent to death.

Bacteriologic tests are certainly of value in these cases, but absence of bacilli does not demonstrate beyond a doubt the absence of tuberculosis, especially since these cases are often ambulant and frequently do not come under observation under circumstances admitting of methods of bacteriologic diagnosis being employed. This was significantly illustrated by the case reported by Dr. **Belfield**. In view of possible medico-legal complications it is well therefore for the practitioner called to a case of seeming opium poisoning without a clear history, to bear in mind the possibility of meningeal tuberculosis. As Dr. **Weber** indicates, the ptomain of the bacillus tuberculosis plays no small part in determining the symptoms mimicking opium coma. In all probability it is assisted in playing this role by the sudden occurrence of renal inadequacy.

THE ANTITOXIC PROPERTIES OF BILE.

That bile, as secreted by the liver, is not essential to life, is shown by a number of facts, such as obstruction or obliteration of the biliary passages, excision of the liver, biliary fistulæ, etc. Whether under these circumstances the functions of the bile are replaced or compensated for by the activity of some other organ or organs, is not known. It has been thought that suppression of the biliary secretion results in two groups of symptoms: Those of cholemia, arising from the retention of bile in the liver and its resorption into the blood; and those of acholia, arising from the absence of bile from the intestinal tract. These symptoms will be the more pronounced in accordance with the abruptness of their onset and it is possible, under certain conditions, that they may lead to a fatal issue. Gradually induced, however, the system seems capable of adapting itself to the new order of things, and the disturbance of function may be slight and inconspicuous. Permanent retention of bile will of course be attended with chronic jaundice.

Of late years the opinion has gained ground that the bile plays only a subordinate part in the process of intestinal digestion. being rather accessory to the functions of the pancreatic juice. It aids especially in the emulsification and saponification of fats, and through its alkalinity favors the passage of the products of these processes into the vessels. It possesses, further, some degree of antiputrefactive power, as well as peristaltic activity. That it may have besides other and not less important functions, such as rendering innocuous toxic substances that gain entrance into the gastro-intestinal tract would seem indicated by some c[illegible] [illegible] ri[illegible] [illegible]dical

Journal, July 17, 1897, p: 125) in the course of investigations into the means by which the toxic activity of the venom of poisonous snakes may be neutralized. The liver has always been looked upon as the filter or gateway through which must pass poisons and other substances introduced into the stomach and bowels, and it may be developed that its usefulness in the direction of neutralizing the deleterious effects of such substances may be shared by the product of its activity, the bile.

It is well known that serpents' venom and toxins of various sorts introduced into the stomach of both lower animals and man do not give rise to the profound toxic effects that follow their injection beneath the skin. This peculiarity may be due either to the chemic activity of the gastric and intestinal secretions, or to failure of absorption. It is appreciated that the toxicity of the substances named is not materially diminished by gastric digestion; further, absorption from the stomach is very slow. That absorption from the intestine is unattended with symptoms of intoxication may be due to the chemic or physiologic action of some substance or substances present in the intestinal canal, most probably the bile or the pancreatic juice. As the result of an inquiry into this aspect of the subject **FRASER** found that the bile was capable of exercising a profound neutralizing influence upon several varieties of venom. The experiments consisted in mixing the bile of a venomous serpent with a lethal dose of venom and injecting the mixture beneath the skin of an animal. When the admixture of bile was sufficient, death did not take place. Similar results were secured with the bile of non-venomous serpents, although they were not equally pronounced. It would thus appear that the bile possesses distinct antitoxic powers.

Various facts tend to show that innocuous as well as venomous serpents possess poison-glands and secrete venom, but the former are innocuous because they are not normally supplied with weapons of offense in the form of poison-fangs. Most probably, therefore, the relative protection against the toxic action of venom introduced into the circulation, which is common to all serpents, is dependent upon an effect due to the venom secreted, in the case of the innocuous serpents only in relatively small quantity. In conformity with this fact, a larger quantity of bile from the latter was necessary to prevent death from injections of venom. The bile of oxen, rabbits and guinea pigs possesses a similar influence, though milder in degree. This difference in potency, it is thought, must be dependent, at least in part, upon some specific constituent or constituents present in different quantities in the bile of different animals. In the hope of isolating these, the bile of a venomous snake was treated with alcohol and the substances soluble in this separated from those insoluble. To the latter water was added and the resulting solution centrifugated and evaporated to dryness over sulphuric acid in the vacuum of an air pump. The alcoholic solution also was dried, at first over a water bath at a temperature of 100 degrees F., and afterward *in vacuo* over sulphuric acid. The product obtained by the second procedure proved incapable of preventing death from lethal doses of venom, while that obtained from the watery solution exhibited distinct antitoxic powers. It is thus shown that the antitoxic properties of bile reside in substances soluble in water.

Although bile in the alimentary canal is non-toxic, it is quite otherwise when introduced beneath the skin or directly into the circulation, and the deleterious effects would be all the more pronounced if such a quantity were injected as would be necessary to neutralize the influence of venom previously injected. The isolation of the antidotal principle or principles, however, makes it possible under such conditions to employ a sufficient dose without evil results.

FRASER notes the interesting fact that bile enters into the composition of the medicines most trusted in for the treatment of snake bite by the natives of Africa, both by topical application and by internal administration.

As has been stated, other toxins introduced into the stomach also are inert, and it may be, as with serpents' venom, that this effect is due to the influence of the bile. Further, the same influence may be responsible for the prevention of various forms of auto-intoxication through the gastro-intestinal tract.

THE STUDY OF ALCOHOL.

It will be new to our readers to learn that alcohol in all its many aspects is receiving unusual attention this year from scientists and medical men. The congress at Moscow has set apart a section on alcoholism, and the advance program announces six papers and discussions on various phases of this topic. A distinct congress called the International Congress Against the Abuse of Alcohol, meets at Brussels, Belgium, in September next, for the fifth annual meeting. This gathering includes a large number of eminent medical men, and also philanthropists, who discuss this subject in a very scientific business-like way, without much sentiment or theory. The French Academy of Medicine and the Chamber of Deputies have taken up the subject, and many papers and discussions have been offered which have occupied a great deal of time. All the secular papers and medical journals have, and are yet discussing the causes and remedies of the increasing alcoholism and pauperism of the country. Studies of alcohol on the body in health and disease have already begun, and papers are appearing in nearly all continental Europe condemning alcohol and showing its evil effects. The medical society of the Rhine Provinces recently took up the use of alcohol in medicine and passed strong resolutions against its use except under certain special conditions. In Russia, Sweden and Norway, medical societies have taken the same position and are agitating the subject in statistical papers and discussions.

In England a bill is before Parliament giving greater powers of control over inebriates, and the leading journals, both secular and medical, publish very strong radical articles on this subject. The two medical societies, one devoted to the action of alcohol in medicine and on the body, and the other to the study and care of inebriates, are becoming larger and more popular and their papers and publications are increasing yearly.

In this country two similar societies exist, one the association for the study and cure of inebriates (the first society of medical men ever formed to study this subject), the other the medical temperance association, are bringing the questions concerning alcohol and the inebriate to the attention of physicians everywhere. As an evidence of the great interest being created in this subject *Appleton's Science Monthly* has published five long papers so far this year on alcohol and the inebriate. For years the annual meeting of our ASSOCIATION has brought out many papers on these topics, which have been accepted as scientific and valuable. In this there is no reference to the armies of temperance and philanthropic persons who urge a continual crusade against all use of spirits. This is only an outline of the medical work and efforts to ascertain the real facts. The question is to reexamine the entire subject of alcohol and the inebriate in the new light of science, and above the levels of theory and opinion. This is the province of physicians in their various fields of practice. The laboratories may show how spirits act on animals and on the general functional and organic activities of the body, but the practitioner must put these questions to their final test.

It is a source of pleasure to note that medical men in this country lead all the world in the study of the inebriate. American laboratory studies of alcohol are still behind the French and German work. During the past year several very prominent experimental studies have appeared and the hope is expressed that more will follow. An effort is being made to endow a chair of experimental work in this field alone in an Eastern university. This will succeed after a time and we shall expect to find American physicians in the front on all lines of this new and most important field of study.

CORRESPONDENCE.

Blood-letting.

SAN FRANCISCO, CAL., Sept. 10, 1897.

To the Editor:—I am led by the excellent paper of Dr. J. W. Hoff on "Blood-letting as a Therapeutic Remedy," in the JOURNAL of August 28, to add some experiences that I have had with the lancet. I will premise by saying that my father was a student of Dr. Benjamin Rush of the University of Pennsylvania, class of 1809, and an advocate for the free use of blood-letting, then thought so essential in the sthenic diseases of the West. When preparing myself for the study of medicine I bled for him very often. But after the epidemic of cholera in 1833 he said the type of diseases was so changed that his patients did not bear the loss of blood as before, an opinion I have since found expressed in the valuable work on the practice of medicine, by Sir Thomas Watson. My father consequently rarely bled. Following his example, lancets rusted in my pockets, and for a long time a doctor who had lost a patient after venesection (and who of us has not read the harsh censure of Dr. Craik for its use in the case of General Washington?) would have been tabooed as an old fogy, if not dealt with more energetically.

I lived in one of the best mining districts of California the first two years after the discovery of gold. Only in the rainy season could the miners get water to wash the dirt they had thrown up in the dry season on the banks of the gulches. This water was as cold as ice and snow could make it and the men, a hardy set who lived on coarse food, were of full plethoric habits, suffered much from acute inflammatory rheumatism. Bear in mind this was nearly fifty years ago, and I hope your readers will not be shocked when I tell them that my custom was to set these tough fellows up in bed, when the violence of the attack did not preclude the possibility of doing so, open a vein and bleed almost to syncope; then, after free catharsis, give from two to four drams of nit. potassa in flax tea or gruel for a drink every twenty-four hours, a practice that gave me entire satisfaction, as not a single case, as far as my knowledge went, ever suffered subsequently from heart complications, although such were rife among them from other causes, as lifting boulders, sluice boxes, etc.

I will only mention two comparatively recent cases of recovery after blood-letting. I was called to see a 13-year-old son of Mrs. H., an intelligent German woman, who had been aroused at 3 o'clock A.M. by the harsh croupy cough of the boy. She put him in a hot bath and with the co. syr. squills, soon had him breathing easily, but in an hour the harsh croupy cough and dyspnea returned. She repeated the bath and medicine with a like result, followed in an hour or two as before. When I saw him at 7 A.M. he was unable to lie down, had a hard metallic cough and an anxious cyanosed expression of face. The treatment was supplemented by calomel, nauseants, bromids and counter-irritants with no apparent benefit. As a resort dernier I bled him, and before I had drawn a half a pint of blood he lay down, the symptoms all subsided, and he made a good recovery. Not long after that I was requested by Dr. S. to see with him Mrs. P., a primipara, the young wife of Dr. P., a former pupil of his. This was at 8 P.M. At midnight, twenty hours before, upon the termination of labor she went into convulsions and Dr. S. was called. He gave chloroform, chloral and morphia, but the convulsions went on every half hour. He sent for his partner and during the next day six others—all of our leading physicians—saw her, each advising "a little more grape, Captain Bragg." When I examined this moribund woman there were five of us present, one of whom gave a positive dissent when proposed venesection, but being overruled it was agreed that if I would perform the operation it might be done, as everything else had been tried upon the hypothesis of epileptic eclampsia. The lady's family were homeopathists, and it looked like taking desperate chances when I took the responsibility and opened a vein in the right arm, being careful to keep my fingers on the left radial arter[illegible] Before I had drawn a pint of blood the [illegible] brea[illegible] stopped, the hard pulse softened, the [illegible] and blanched and there was not another convulsion. A speedy recovery followed a large enema of oil and turpentine, and I had the pleasure of receiving a most grateful letter from her husband, Dr. P., in which he said the bleeding saved her life. It is to be regretted that a remedy so potent for good, when judiciously used, should have gone into, I will not say "*innocuous* desuetude." Men like Sir Thomas Watson and students of the great father of American medicine, did not mean to discard it, but honestly drew the attention of the profession to those changed conditions which called for care in its use; but extremists, liked Bennett, would have none of it in any case. A careful study of this writer, long ago convinced me that in the cases he reported in which he had bled with bad results, he showed almost a culpable ignorance of the conditions which would justify the use of the remedy, and the same want of discrimination has led many to fall into line with him.

It will be sixty years next March since I began the practice of medicine, and within that time I have heard and read almost every old standard remedy condemned by respectable graduates of our medical schools; one would not bleed under any circumstances; another would never blister; another would not give calomel; another would never give an emetic except in a case of poisoning, and recently one of our ablest physicians decried the use of opiates, and so on. Wishing not to be uncharitable, I believe that in each case the fault lay in the limited knowledge of the widest therapeutic range of the respective remedy condemned, together with a slavish following of text-books, when their diagnosis had been made without due consideration of age, temperament, habits of life or stage of disease; and has not the search after specifics for the last twenty years had something to do with the neglect of our old armamentarium? F. WALTON TODD, M.D.

Improved Method of Cocain Anesthesia.

DALLAS, TEXAS, Sept. 4, 1897.

To the Editor:—With the permission of Drs. Anderson and Oaks, I would like to add something in reference to the "Improved Method of Cocain Anesthesia" by Dr. P. L. Anderson. This is not in the nature of criticism, but simply to add my experience to theirs.

In 1890 it seemed to be the practice to use a 4 per cent. solution of cocain with a spray for this purpose, but I did not adhere to this, for I soon found that the toxic effects of the drug were alarming and began applying it by means of cotton wrapped on a cotton carrier. I did not at this time (1891) use the preliminary spray, but gradually increased the strength of the solution of cocain until finally a saturated solution was used. From this mode of application I did not notice any special toxic effect, except in very susceptible patients; in fact, it was so much less than previously that I thought I had an ideal method. Of course my previous experience taught me that its effects at times were very unhappy, and I used great caution in its application. The inexperienced should first be acquainted with the toxic effects of the drug. The word "caution" to a careful observer is the same as a green flag or a green lantern to a careful locomotive engineer—it means caution. I am inclined toward the belief that Dr. Oaks' grave apprehensions are not well founded, because there is no recent graduate of today, or even inexperienced physician, unless he is not abreast of the times, who is not acquainted and does not know that cocain is dangerous. To them it is only necessary to say a word of caution.

The saturated solution is prepared as follows: A small portion of cotton placed upon the end of a probe is saturated with water, the excess being wiped off; crystals of cocain placed in a watch-glass, or on the bottom of a medicine glass, are then rubbed up with the wet cotton, which is allowed to take up the cocain to its fine capacity. It is applied to the part to be operated upon by rubbing it against it until the patient decides that the part is perfectly insensible. If the nose pours out an abundance of mucus, this procedure must be repeated, rarely three times, which usually produced toxic effects by the secretion spreading over a greater surface. The flow of mucus prevents rapid absorption at the point desired, probably by diluting the drug. This mode of application is about the same as that advocated by Dr. Anderson, except he used 25 and 50 per cent. solution, while I used the saturated. In this way I got an absolutely fresh, as well as a saturated solution. This mode of preparing the solution was done for two reasons: 1, to get a fresh solution; 2, to do away with the necessity of throwing the cotton away if a repetition of the procedure was necessary, which in a very strong solution was considerable waste. At the end of a year or so this proceeding was partially abandoned, not because of toxic effect or insufficiency, but because it was too much trouble, and there was always more or less reaction following the slight injury to the membrane. In its place I began the preliminary use of a spray of 1.5 per cent. solution in 4 per cent. solution boric acid and applied pledgets of cotton saturated in a solution of 6 per cent. strength, which I still use with great satisfaction. I do not use the preliminary spray because it has any special advantage in producing anesthesia of the mucous membrane of the nose in a surgical sense, but because it reduces turgescence and swelling of the membrane; besides, depleting the erectile tissue slightly reduces its sensibility, and this enlarges the nasal passages and allows the cotton pledgets to be passed easily and almost painlessly. It also checks the flow of mucus, which flow greatly interferes with any method of application.

Saturate the cotton and squeeze out the excess by rolling it hard against the mouth of the bottle, and place it against the part to be operated upon, allowing it to remain there while otherwise preparing for the operation. If it is to be a chromic acid application the patient is ready by the time or before the acid is prepared on the applicator. This latter preparation attracts the patient's attention and he usually forgets about the cocain application.

This method of application has been eminently satisfactory in my hands, seldom getting the toxic effect of the drug; more often, however, I get the effect of mental dread upon the patient as he apprehends the operation; which, by the way, appears to be a peculiar idiosyncrasy of men, women succumbing much less often and recuperating more rapidly; a woman will faint much more quickly if witnessing the operation performed upon some one else. I attribute this difference to the fact that women acquire the habit and are taught to endure much more pain and mental strain than men. Her pride, prompted by her sense of humiliation, stimulates her to the position of self-control, which is truly remarkable. It would appear that if this effect is the result of cocain poisoning, men and women would be affected alike.

I still occasionally use the method I formerly used, and that advocated by Dr. Anderson, in anesthetizing the septum, and occasionally the turbinated bones. The time necessary for anesthesia is from three to eight minutes. I more often operate under than over five minutes. In the preliminary step any good spray apparatus is sufficient (I use a spray and instantaneous cut-off devised by myself). A continuous spray for two seconds duration in the anterior nares is sufficient, the patient being told to immediately incline the head forward and down without blowing his nose, which causes the excess to flow out and is caught on a napkin in the patient's hands, then by the time the pledget of cotton is deliberately prepared the preliminary spraying has been effective, and the patient having cleared out the nostrils, insert the cotton with cocain as desired. I can not agree with Dr. Ingals that from fifteen to twenty minutes are necessary to produce anesthesia sufficient for intranasal operations; indeed, the application must be very imperfectly made when this time is required. My patients complain of pain so very infrequently that I take it as a matter of fact that there will be no pain, and assure the patient so. In galvanocautery operations I seldom reach the fifteen minute mark for the completion of the operation, including the anesthesia. I very seldom have waited as long as fifteen minutes for anesthesia.

I always operate in the sitting posture, unless for special reasons I notice an idiosyncrasy or predisposition to fainting, because it is very much more convenient, the patient being able to expectorate and clear the nose in case of hemorrhage. While fainting and toxic effects are somewhat favored by the upright position, hemorrhage is less.

Dr. Anderson is correct in his statement that patients recover more quickly in the recumbent position, whether from the toxic effect of cocain or fainting. I have been compelled twice to place the patient in the recumbent position after having begun the operation sitting. It is not an easy matter to handle a limp patient under such condition; in fact, without an assistant it is at times quite impossible. This occasional unhappy condition in my opinion argues more than all else in favor of the recumbent posture, but the convenience both to patient and operator is certainly in favor of the sitting position.

Spraying the nose with a solution of cocain strong enough to produce anesthesia sufficiently complete for intranasal operations should be unconditionally and emphatically condemned as an unscientific and dangerous procedure.

The manner, then, of application as between placing pledgets of cotton saturated with a weak solution (6 to 10 per cent.) in the nasal cavity, and the method advocated by Dr. Anderson, and formerly practiced by myself, of a strong solution (25 per cent.) to the saturated solution, I prefer the former method because I have found it much more convenient, saves time and is tolerated better by the patient, without increasing the dangers of the toxic effects of the drug.

HENRY W. WANDLESS, M.D.

On the Excretion of Urea.

TIVERTON, R. I., Sept. 10, 1897.

To the Editor:—On page 438 of the JOURNAL, Aug. 28, 1897, Dr. Charles Stover of Amsterdam, N. Y., is quoted as follows: "He also spoke of a case which came under his own observation, in which but 500 grains of urea were excreted daily when there should have been 1,300, the patient developing eclampsia."

I do not remember having read that pregnancy was a particular cause of increased excretion of urea, but consulting my authorities, quotations from a few enclosed, I learn that the normal excretion of urea is about 1 ounce or 500 grains in health. If the above statement of Dr. Stover is a fact, that she should have excreted 1,300 grains, or 2.15 time the normal amount during health, what cause should this great increase of the excretion of urea in pregnancy be ascribed to? Allow me to quote. Bartley ("Med. Chemistry," 4th Ed., 1895, p. 615): This quantity, multiplied by the number of fluid ounces passed in twenty-four hours, gives the amount of urea excreted in twenty-four hours, which should not be far from 500 grains. A less quantity than 350 grains in an adult, who is eating the usual amount, should be regarded as pathologic and suspicious of nephritis or deficient kidney excretion. Robert ("Urinary and Renal Diseases," 2d Ed., 1872, p. 115): The daily separation of urea, by adult men between the ages of 20 and 40, averages about 500 grains; but the amount varies considerably from various causes, such as diet, exercise, meteorologic conditions and individual peculiarities; of twenty-four observations, of not less than six days each, tabulated by Dr. Parkes, the minimum result is 286.1 grains and the maximum 684.4 grains per day. Marshall ("Outlines of Physiology," Ed. 1868, Lea, p. 777): In man, with an exclusively animal diet, the daily quantity excreted was found by Lehmann to be about 820 grains; with a mixed diet, 500 grains; with a vegetable diet, 347 grains, and with a comparatively non-nitrogenous diet, 237 grains. In the female, from her smaller frame, her less active nutrient metamorphoses and the smaller quantity of food consumed, the daily quantity excreted is about three-fourths of an ounce (360 grains). Proportionately to the weight of the body it is less abundantly found in women. Hare ("Practical Diagnosis," 1896, p. 389): Although the quantity of urea varies very greatly in perfect health, the mean amount excreted in twenty-four hours by a healthy man of 20 to 40 years is about 512 grains; women excrete a little less than men. If, therefore, in a pregnant woman or a person suffering from Bright's disease, analysis shows a constant diminution in the amount of excreted urea, the physician is warned that a uremic convulsion or other manifestation of uremic disorder is imminent.

Nor can I find any reference in the standard works of my library to increased excretion of urea during pregnancy. On the other hand, I find many writers referring to eclampsia from other toxic causes than retained urea. (*Vide*, Professor Palmer, "Am. System of Obstetrics," p. 204, also Professor Lusk in his work.) E. P. STIMSON, M.D.

Leprosy in Chinese Laundries.

NEW YORK CITY, Sept. 6, 1897.

To the Editor:—The report of Charles F. Roberts, M.D., Sanitary Superintendent of the Board of Health of New York, to the Hon. Chas. G. Wilson, President, regarding the question of the presence or absence of leprosy in the Chinese laundries of this city, contains statements not consistent with the knowledge of the present day. I have nothing to say about the presence of the disease in the Chinese laundries; I may, however, say I do not believe in its existence. So far he is correct. But I object to his statement that "the authorities of the present day entertain the belief that the disease is due to infection not contagion."

I venture to affirm that all able authorities of the whole world, believe in contagiousness, and that it is as contagious in "the four hundred of New York" as in the slums of Cherry Hill. "The best authorities of this country" do not agree with the report of the Medical Society of the County of New York, a report which was gotten up to back its chairman, Health Commissioner George B. Fowler, in his intent to discharge the lepers from North Brother Island. *These lepers have since been let loose.*

As a matter of expediency for the New York Board of Health that report of the New York County Medical Society, and this report on Chinese laundrymen, are of one piece.

ALBERT S. ASHMEAD, M.D.

Reply to Dr. Paquin.

BUFFALO, N. Y., Aug. 26, 1897.

To the Editor:—I desire a little space to reply to an article of Dr. Paul Paquin written in criticism of my report, on treatment of tuberculosis, presented at the last meeting of the AMERICAN MEDICAL ASSOCIATION. Far from belittling the results of serum-therapy and declaring against the use of tubercle antitoxin, I am heartily in favor of such methods of treatment in suitable cases. The conclusions to which I came in regard to antitoxin are, it seems to me, thoroughly justified and are not materially different from Dr. Paquin's own conclusions: viz., that "in cases of phthisis that are at all advanced it is of no value, that in the *one* case (and I particularly state *one*) of almost pure tuberculosis of larynx and upper lobe in which I used it, it was worse than useless, not having stayed the disease and having produced great physical suffering; that in the case of gland tuberculosis it has apparently done no harm and may yet be of value;" but (here I differ from Dr. Paquin) "that in all cases with the exception of the last, *the pain produced by the injection and the unpleasant after-results in the way of dermatitis and glandular swellings would almost, if indeed not entirely, prohibit its use.*"

The possibility of improvement seems so slight when we consider the pain and suffering produced, especially as we can not definitely promise recovery or even improvement to our patients by the use of this particular serum, that I am not willing to ask patients to undergo the ordeal. So much for Dr. Paquin's criticism of the conclusions to which I have come; as to the more personal matters that he has cared to drag into the question, I have only to say that I was unable to procure any of Maragliano's serum and so could make no comparative test. He implies that I obtained the serum at a reduced rate by making false statements. I reply that I paid full price for the serum as I would not consent to the conditions under which the reduction in price was offered.

As to the slurring reference to my scientific ability, I am perfectly willing to stand on my record among those who know my work. Yours very truly,

DELANCEY ROCHESTER, M.D.

Dr. Paquin's Serum.

ST. LOUIS, Sept. 6, 1897.

To the Editor:—In the JOURNAL of Aug. 21, 1897, Dr. Paul Paquin mentions my name as one of a number of physicians who "used serum and are still using it." There appeared in the *New York Medical Journal*, Sept. 1, 1895, a report by me of a case of tuberculosis, for which I recommended the use of Paquin's anti-tubercle serum. The patient recovered. The report of this case has been used extensively to advertise Dr. Paquin's serum. I made an extensive trial of the serum for some months after the recovery of this patient, but the results were either negative, or they appeared to be similar to those following the use of Koch's old tuberculin. As the serum was injurious and dangerous to my patients, I discontinued its administration. I do not, under any circumstances, wish to be considered as indorsing the Paquin anti-tubercle serum.

Yours very truly, J. R. LEMEN, M.D.

The Use of Goat's Milk.

GROVELAND, MASS., Aug. 10, 1897.

To the Editor:—I should be greatly indebted to any of your readers who would write to me concerning any experience they may have had in the use of goat's milk in the treatment of wasting diseases.

I should also be very glad to receive at the same time professional opinion concerning goat blood serum, as to its antitoxic effect in the treatment of tuberculosis, diphtheria, etc.

Respectfully, WM. THORNTON PARKER, M.D.

ASSOCIATION NEWS.

Section on Surgery and Anatomy.—Minutes of the Section on Surgery and Anatomy at the forty-eighth annual meeting of the AMERICAN MEDICAL ASSOCIATION at Philadelphia, June 1-4, 1897. The Chair appointed as a nominating committee, Drs. DeForest Willard of Philadelphia, H. O. Marcy of Boston, and J. McFadden Gaston of Atlanta. This committee reported as follows: Chairman, Dr. John B. Murphy of Chicago, and Secretary, Dr. William L. Rodman of Louisville. Dr. Murphy having been selected to deliver the "Address on Surgery" next year, resigned the Chairmanship of this Section and it was moved that the nominations to fill the vacancy should be filled by ballot. Carried. The following were then nominated: Dr. Wm. L. Rodman, Louisville; Dr. H. O. Walker, Detroit, and Dr. W. J. Mayo, Rochester, Minn. After three ballots Dr. Rodman was declared elected. The following nominations were then made for Secretary to succeed Dr. Rodman: Drs. Clayton Parkhill of Denver and McLane of Detroit. Dr. McLane withdrawing, Dr. Parkhill was declared unanimously elected. It was moved and seconded that in the future the Nominating Committee shall be continued until the end of the session for which they are appointed to serve. Carried. It was moved and seconded that all papers read by title because their authors failed to read them shall be excluded from the "Transactions," except where such failure to read papers is due to the death of the author or to lack of time on the part of the Section. Not carried. It was moved and seconded that a committee of five should be appointed to consider Dr. Senn's proposition of the previous day and report the next morning. The Chairman appointed Drs. Nicholas Senn of Chicago, G. R. Fowler of Brooklyn, H. Augustus Wilson of Philadelphia, J. McFadden Gaston of Atlanta, and J. D. Griffiths of Kansas City, Mo. Dr. Senn declining to serve, Dr. H. O. Walker of Detroit was added to the Committee. (*Vide* JOURNAL, June 26, July 17, etc., for the Committee's report.) It was moved and seconded that the name of Dr. R. J. Reed of Wheeling, W. Va., should be inserted in the "Transactions" as Secretary *pro tem.* of this meeting instead of Dr. Bayard Holmes' name (owing to Dr. Holmes' absence). Carried. It was moved and seconded that a vote of thanks should be extended to the Chairman of this meeting.

Notice to Secretaries.—In order to enable the officers of the ASSOCIATION to know what societies are in affiliation with the ASSOCIATION, the secretaries of every State medical society are urgently requested to forward to the Permanent Secretary, W. B. Atkinson, M.D., 1400 Pine Street, Philadelphia, as early as possible, a complete list of the local or district societies which are "recognized by representation in the State society."

SOCIETY NEWS.

The Tri-State Medical Society of Alabama, Georgia and Tennessee will hold its ninth annual meeting in Nashville, Tenn., October 12, 13 and 14.

The American Association of Colored Physicians.—The annual session for 1897 will be held in Nashville, Tenn., October 15 and 16. The program offers thirty five papers by the leading negro physicians throughout the United States.

The Third International Congress of Sociology convened at Paris in July, with Senator Lilienfeld of Russia in the Chair. According to the *Progrès Méd.*, the most important address was delivered by Prof. Lester Ward of Washington, D. C., on the "Economics of Pain and the Economics of Pleasure."

The Medical Society of Virginia held its twentieth annual session at Hot Springs, Va., September 1, 2 and 3. The society was organized by ninety-two physicians, Nov. 2, 1870; of these twenty-seven are still living. The society now has a membership of 854. At the recent meeting prizes were awarded the competitors who had submitted essays on Virginia medical history. An original prize of $450 was awarded to Dr. Jordan of Richmond, while supplementary prizes of $100, $75, $50 and $25 went respectively to Drs. Hugh Cummings, non-resident fellow, of Philadelphia, Hugh M. McGuire of Alexandria, Jessie Ewell of Richmond and W. T. Walker of Lynchburg. George B. Johnston, M.D., president, in his address, contended for State Medical Societies and pointed out their good results to the profession and public. The question of the admission of women as fellows of the society was settled in their favor with little opposition. The following officers were elected: President, Dr. Lewis E. Haine, Danville; first vice-

president, Dr. L. G. Pedigo, Crockett Springs; second vice-president, Dr. A. S. Rixey, Culpeper; third vice-president, Dr. H. F. Cline, Front Royal; recording secretary, Dr. L. B. Edwards, Richmond; treasurer, Dr. R. T. Styll, Petersburg; corresponding secretary, Dr. John F. Winn, Richmond.

The Congress of Hygiene and Climatology for Belgium and the Congo, recently held at Brussels, was principally devoted to the recommendation of hygienic measures already adopted by other countries, and the question of acclimation in the Congo. We note that colonists from the north of Europe, Swedes, Norwegians, etc., are more apt to thrive than Italians, Spaniards, etc. The nervo-sanguine temperament is the most resistant to the climate, and the age between 25 and 35. The best season to arrive is in the dry, cool months of July, August and September. Negroes imported from South America, whose ancestors came from the Congo region, succumbed rapidly to malaria and dysentery, showing that the immunity had not been inherited. The annual mortality among the negroes working on the railroad is now only fifty per thousand, while there was a brief time when, from lack of suitable food and shelter, it rose to 900 per thousand. Bonkowsky Pasha represented Turkey at the Congress. He stated that the Sultan is much interested in hygienic matters, and that although the sanitary arrangements of the Red Sea and in Arabia are not complete, yet they had succeeded in arresting the spread of the plague in two months after it had appeared at Mecca; also that the cholera had not appeared in an epidemic form since 1895. Belgium is the first country to introduce a complete ozonometric service, and further study by similar scientific methods was urged on all countries.—*Gaz. Méd. de Liège*, August 19.

American Electro-Therapeutic Association.—The following papers will be read at the next annual meeting of the American Electro-Therapeutic Association at Harrisburg, Pa., Sept. 21, 22 and 23, 1897: Caleb Brown, Iowa, "Electricity as an Aid in the Treatment of Goiter;" Francis B. Bishop, Washington, D. C., "Chorea;" Lucy Hall Brown, Brooklyn, "A New Electrode for Use with Static Machine;" Eugene R. Corson, Savannah, "Some Thoughts and Suggestions on X-Ray Work;" Margaret A. Cleaves, New York, "Expenditure of Electrical Energy;" Prof. A. E. Dolbear, Boston, "Molecular Effects of Electricity;" William J. Herdman, Ann Arbor, "The Influence of Magnetic Fields on Nutrition;" J. H. Kellogg, Battle Creek, "Electricity as a Means of Involuntary Exercise;" Charles H. Lodor, Chicago, "The Treatment of Urethral Hyperesthesia in the Male;" Robert S. Newton, New York, "What Has Electricity Accomplished in the Treatment of Mental Diseases?" Robert Newman, New York, "Electric Treatment in Gout and Uric Acid Diathesis;" R. J. Nunn, Savannah, "Sources of Atmospheric Electricity;" Curran Pope, Louisville, "The Electro-Therapeutics of Neurasthenia;" F. H. Wallace, Boston, "Ozone in Nasal Catarrh and Pulmonary Diseases;" W. S. Watson, Fishkill-on-Hudson, "Medical Electricity;" L. A. Weigel, Rochester, "Electricity in Orthopedic Practice;" G. B. Massey, Philadelphia, "The New Electro-mercuric Treatment of Cancer;" J. Bergonié, Bordeaux, France, *a*, "A New Electrode, Preventing the Diffusion of the Current;" *b*, "Palliative Electric Treatment of Tic Douloureux of the Face;" *c*, "The Action of the Roentgen Rays on the Vitality and Virulence of Koch's Bacilli in Cultures." There is a good prospect of having a fine exhibit of electric apparatuses and also several social entertainments and receptions.

PUBLIC HEALTH.

Yellow Fever.—In our last issue we referred to the efforts that were being made by National and State authorities to arrest the spread of the epidemic at Ocean Springs and the coast of the Mississippi Sound. We stated (page 552) "the number of cases that is reported makes it probable that even the best directed efforts will not avail to prevent other cases here and there. Prompt isolation of these cases, which will occur this week, if at all, will prevent a further spread."

It now seems that the separate cases which have appeared, with the single exception of New Orleans, were not promptly isolated, and we may well fear that we are on the verge of an extended epidemic. According to the newspapers, on September 6 there have been 600 cases of various kinds of fever at Ocean Springs. There was one case of yellow fever reported at Edwards, Miss. On the 7th there were twenty-two new cases reported, namely, New Orleans five, Scranton sixteen, one refugee died at Louisville; on the 8th three new cases were reported at Biloxi with one death. The actual number of cases of yellow fever at Ocean Springs was then officially declared to be but 20. On the 9th it was stated that there had been a total of 748 cases of yellow fever at Ocean Springs from July 8 to September 9. Nobody, it seems, paid any particular attention to it during July and August and persons went in and out of the Springs as usual. On September 10 there were twelve "suspicious" cases reported at New Orleans and seven new cases at Biloxi. It subsequently appears that on September 13 thirteen cases were reported from Mobile, and it seems that the fears which were entertained the first of last week will unfortunately be realized. It is said that all cases have been attributed to Ocean Springs, with the exception of one case at the City Hospital in Mobile. Four cases were reported at Berkley, and Surgeon Carter gives it as his opinion that there have been ten cases, with four deaths, of yellow fever at Berkley. It thus appears that nearly all the cases have been developed from the original center at Ocean Springs.

In this connection it will be recalled that Congress some years ago directed the removal of the National Quarantine from Ship Island to Chandeleur Island, in order to prevent epidemics of this character, on the recommendation of Surgeon-General Hamilton. On the 13th seven new cases were reported at New Orleans, two cases at Galveston, Texas, and six new cases at Ocean Springs. Isolation, which would have been successful had it been applied early, is thus made extremely difficult of execution. The best hope for the people at this juncture is in immediate depopulation of the non-immune, and their escape to the high country. Atlanta, which has always opened its doors in cases of yellow fever epidemics, will, it is understood, pursue the same course this year. Its elevation, 1,600 feet, is such that it is believed, while yellow fever may exist among those arriving while sick, it is not likely to spread. Chicago opened its doors in 1878; thirty-six cases were treated here and no spread of the disease occurred. It is believed that the nights are too cool in the towns along Lake Michigan for yellow fever. Food for the fever now existing in the South should be removed at the earliest possible date as frost is not likely to occur along the Gulf Coast until November.

P. A. Surgeon Wasdin was reported sick on September 13, and the Texas quarantine at Sabine Pass damaged by a cyclone.

Protection of the Milk Supply by a Local Board of Health.—Minneapolis is one of the small number of cities in which the health authorities have undertaken to prevent the sale of milk from consumptive cows to the people under their jurisdiction, by requiring the dairy farmers who ship milk to the city to prove that their herds have been purified by means of the tuberculin test. One farmer rebelled against this requirement and appealed to the courts upon the ground that the city's board of health had no right to enforce such a regulation with respect to herds kept outside the city limits.

Health in Chicago.—*During* August the total number of deaths was 1,967 or 1.21 per 1,000, as compared to 1.40 per 1,000 in August, 1896. Of these deaths 755 were persons under 1 year, and 303 between 1 and 5 years old. The principal causes were: Infantile diarrhea, 362: other acute intestinal diseases, 360; diseases of the nervous system, 207; consumption, 153; diseases of the heart, 97; pneumonia, 66; cancer, 57; diphtheria and membranous croup, 47; typhoid fever, 42; and bronchitis 41 deaths.

The Arbitrary Power of Health Boards receives a handsome apology from Dr. H. M. Biggs of New York, in a paper read before the British Medical Association September 3. He says that "the belief is never aroused in any class of the population, however ignorant, that the institution or enforcement of any sanitary measures is designed for the restriction of the individual freedom. There is nowhere to be found any jealousy or distrust of law and government as such. It is therefore possible to adopt measures more arbitrary in many respects than could be adopted in most other countries, simply because our government is democratic. This is the keynote to the attitude of the sanitary authorities of New York.

NECROLOGY.

JESSE OREN, M.D., at his home in Laporte City, Iowa, August 25, 1897, of diabetes, aged 73 years. He studied medicine under Prof. James Bryan of Jefferson, was graduated from Pennsylvania Medical University in 1854, practiced a short time in Philadelphia, then entered the Russian service and served on the Russian staff as surgeon during the Crimean war. After the war ended he returned to Philadelphia and moved to Iowa in 1856. In 1858 he moved to Laporte City, where he made his home the remainder of his days. Dr. Oren was promoted while in the Russian service to the rank of Major, and was also made a present of twenty-five rubles by Czar Nicholas for excellent services.

J. M. SWIFT, M.D. The death of Dr. J. M. Swift of Northville, Mich., an honorary member of the Wayne County (Mich.) Medical Society was reported at a recent meeting of that Society, and on motion a committee was appointed by the President to draft suitable resolutions in respect for him. They are as follows:

The man who exerts himself to do good and helps to build up the commonwealth deserves the good will of his friends and neighbors while living, and when he has been called to join the great majority, he should be held in pleasant and appreciative memory by all who have known him. Dr. Swift, we know, was held in high esteem, and we, the members of this Society of which he was an honorary member, do here record the fact that we cherish the memory of our departed friend and brother, and
